

2003 EIS

1 tank residuals causing a later secondary peak, and with long-term releases from solid wastes, including
2 ILAW, appearing during the last several thousand years of the 10,000-year post-closure analysis.
3 Figure S.19 illustrates these results.
4

5 SAC was also employed to evaluate the relative role in overall release of different waste types,
6 including solid waste, past liquid discharges, past tank leaks, future tank losses, tank residuals, unplanned
7 releases, and facilities including canyon buildings. The variability in the results is due to variability in the
8 inventory, release, and transport of the contaminants. In the simulation, the contribution to technetium-99
9 from solid waste releases to groundwater would amount to approximately 20 percent of the cumulative
10 release from all Hanford sources. For uranium, releases from solid waste to groundwater are much lower.
11 The majority of the technetium-99 and uranium releases from wastes (other than ILAW) were predicted
12 to occur from liquid discharge sites (e.g., cribs, ponds, ditches) used in the past and from unplanned
13 releases on the Central Plateau and from off-plateau waste sites.

21 **Uncertainties**

22
23 Even with the knowledge gained over the past decade in addressing our environmental cleanup
24 challenges, there still are a great many unknowns. Waste site inventories, both in terms of chemical and
25 radioactive contaminants, are not precisely known for many of the solid and liquid wastes sites present on
26 the Central Plateau. Although the overall quantities of radionuclides generated at the Hanford Site are
27 relatively well known, the actual amount in specific waste sites is uncertain. In addition, the long-term
28 performance of our in-place waste site remedies and closure techniques is largely unproven. The analysis
29 conducted within the HSW EIS employed a range of models and techniques, each with its own set of
