E.1.0 INTRODUCTION AND METHODOLOGY

This appendix describes the current safety concerns associated with the tank waste and analyzes the potential accidents and associated potential health effects that could occur under the alternatives included in this Tank Waste Remediation System (TWRS) Environmental Impact Statement (EIS).

Current Tank Safety Issues

The 177 underground storage tanks and approximately 60 active and inactive miscellaneous underground storage tanks (MUST) included in the TWRS contain a wide variety of waste that has numerous safety concerns associated within their current condition. The principal safety issues associated with maintaining an adequate margin of safety for tank farm operations include flammable gas, noxious vapor, organic solvent, organic complexant, ferrocyanide, high-heat, criticality, and tank structural integrity. An accelerated safety analysis (ASA) is currently being developed that will more completely define the current hazards, provide a thorough accident analysis, and develop associated operational safety requirements (controls) that, when implemented, will provide an adequate safety margin for tank farm operations. A summary and status of the TWRS Safety Program, including current hazards and accident analysis, safety issues in progress, and the approach for their resolution is found in a document entitled TWRS Safety Basis (Lipke et al. 1995). The text from that document is presented nearly verbatim in the remaining paragraphs of Section E.1.0.

Historically, the Hanford Waste Tank Safety Program focused on resolving specific safety issues that were identified from a variety of sources. These issues include flammable gas, noxious vapor, organic solvent, organic complexant, ferrocyanide, high-heat, criticality, and tank structural integrity. The approach to evaluating waste tank safety concerns included developing a safety basis by applying safety analysis methodology. The TWRS ASA will provide the necessary documentation to define the safety margin for conducting safe tank farm operations.

The results from the ASA will demonstrate that the waste tanks can be safely managed with the appropriate controls as specified in the Interim Operational Safety Requirements (IOSRs). Continued characterization by sampling of the waste will be used to 1) further confirm the models of waste behavior used in the safety analysis; 2) reduce the uncertainty associated with the calculations; and 3) confirm the conservatism of the source-term data used in the analysis. This additional characterization information will provide the basis for confirming, reducing, or eliminating controls presently in place through the IOSRs.

Safety Issues

Several tank farm safety issues have been previously identified and progress has been made to resolve and close these safety issues with the appropriate documentation and/or controls. The major safety issues are related to the potential for flammable-gas generation, storage, and release, organic solvent combustion reactions, exothermic ferrocyanide-nitrate reactions, deflagration associated with organic complexants, criticality, high-heat generating waste, and tank structural integrity. Identifying and making progress toward resolving of these safety issues helped focus attention on the fact that the original safety basis for the Hanford Site waste tanks was lacking and that specific controls needed to be implemented to ensure that the health and safety of the public, workers, and environment were being adequately protected. Resolution of the remaining safety issues requires gathering information from laboratory energetics and waste degradation studies, assessing of existing sample data, evaluating historical data, and using various waste tank models to predict waste thermal behavior.

Safety Analysis

Developing the safe operating margin for the tanks system required integrating the current evolution of characterization data and understanding the safety issues to conservatively develop the safety basis for continued waste storage. An Interim Safety Basis (ISB) document was issued in November 1993 to establish the authorization basis for the tank farm facilities as part of implementing the U.S. Department of Energy (DOE) Order 5480.23, Nuclear Safety Analysis Reports. The ISB provided the basis for interim operations and controls until an upgraded Safety Analysis Report (SAR) for the tank farm facilities is completed.

Because of the importance of the safety issues associated with the Hanford Site waste tanks, a strategy was developed in mid fiscal year (FY) 1993 to accelerate the hazards and accident analyses for the waste tanks. Developing a full SAR that addressed each of the topics specified by the DOE order would follow, based on the completed hazards and accident analyses.

Application of Data to Determine Source-terms - Because of the variability of waste in the waste tanks, conservative assumptions were used to develop an upper bound for safe operations. Radiological and toxicological source-terms were developed from a combination of theoretical models, recent characterization sampling, and historical sample data. Existing data were evaluated from all sources to determine representative and bounding source-term concentrations for radioactive isotopes and hazardous chemical species. Data from further waste characterization efforts will result in reducing the conservatism in the source-terms used in the ASA analysis.

Development of Safety Envelope - The safety analysis as documented in a SAR for a nuclear facility is intended to define an operating margin or envelope including necessary controls to ensure that the facility can be operated, maintained, shut down, and decommissioned safely in compliance with applicable laws and regulations. The ASA documents the hazards and accident analysis information that will be used in the upgraded Hanford Site tank farm SAR. The ASA systematically identifies facility hazards, selects accident scenarios, and evaluates credible accident scenarios analyzed for potential consequences. When the ASA is approved, the results of the hazards and accident analyses, in combination with the IOSRs, will define the facility's safety envelope. Selecting safety class equipment and performing unreviewed safety question (USQ) determinations will be based on this safety envelope. Results presented in the ASA indicate that the tank farms can be safely maintained within acceptable bounds using appropriate design features and controls.

The hazards analysis validated that the selection of accidents analyzed in the ASA was an appropriate spectrum of bounding and representation events, which are known as evaluation basis accidents (EBAs). The hazard evaluation process also provides a thorough qualitative evaluation of the spectrum of potential accidents involving identified hazards.

The hazards analysis considered a comprehensive range of potential process-related hazards as well as those hazards associated with internal and external events for all 177 waste tanks. The hazards analysis forms the basis for understanding facility worker protection, environmental protection, selecting or confirming potential EBAs to be further developed and quantified, and determining the facility hazard classification.

The analysis results of the selected EBAs provided the basis for developing controls needed for protecting the public and co-located workers. The unmitigated consequences and associated likelihood of the EBAs were compared to the Hanford Site management and operating contractor's risk acceptance guidelines. If the unmitigated consequences and likelihoods exceeded the risk acceptance guidelines, appropriate design features, safety systems, structures and components (SSCs), or administrative controls were identified to reduce the consequence or frequency of the accidents to acceptable levels.

Each EBA was described in the following order:

- Accident scenario;
- Accident frequency;
- Radiological source-term and unmitigated consequences;
- Toxicological source-term and unmitigated consequences;
- Mitigated or prevented radiological consequences;
- Mitigated or prevented toxicological consequences; and
- SSCs, design features, or controls required to meet risk acceptance guidelines.

Table E.1.0.1 provides a list of the EBAs that were analyzed in the ASA and for which radiological and toxicological consequences were determined.

Table E.1.0.1 List of Evaluation Basis Accidents Analyzed in Accelerated Safety Analysis

A primary purpose of the accident analysis is to identify whether SSCs, design features, or controls are required for preventing or mitigating postulated accidents. By including this information in the evaluation basis accidents documentation, safety functions that required consideration for the IOSRs were easily identified. The IOSRs included the definition of acceptable conditions, safe boundaries, basis thereof, and management or administrative controls required to ensure safe operation of the tank farms.

Operational Controls

The accident analysis of the ASA calculated the consequences for unmitigated accidents and identified a range for the accident sequence event frequencies. For each accident sequence, if the consequence and frequency were outside of the risk acceptance guidelines, additional physical and/or administrative controls were established that would either prevent the postulated accident or reduce the calculated consequences or likelihood of the accident. The controls will be incorporated into the IOSRs (technical safety requirements when the SAR is completed) for the facility.

An example of the controls are those used for tanks containing flammable gases. The unmitigated consequences and associated likelihood of a flammable gas deflagration with a tank dome collapse were above the risk acceptance guidelines. Therefore, controls were developed to prevent a gas deflagration. The controls specifically addressed flammable gases accumulating within the tank vapor space, monitoring vapor space flammability concentrations, limiting or preventing ignition sources, and minimizing intrusive activities to reduce hazard exposure.

Safety Relationship with Characterization

The objective of safe waste storage and disposal requires that the waste tank characterization strategy be structured to provide priority support to addressing tank farm safety issues in the most efficient manner.

The Safety Program and characterization approach for resolving priority safety issues related to flammable gas, noxious vapor, organic solvent, organic complexant, ferrocyanide, high-heat generating waste, criticality, and tank structural integrity has been influenced by the progress made to date. The progress includes 1) completing safety analyses for flammable gas, ferrocyanide, criticality, organic solvent (tank 241-C-103), and sludge dry out; 2) successfully mitigating tank 241-SY-101 safety issues; 3) demonstrating actual and simulated waste energetics; 4) demonstrating waste degradation (aging resulting in lower energy products) in laboratory experiments and limited waste sampling for ferrocyanide and organics; 5) completing laboratory tests to define conditions required for condensed phase propagating reactions, and 6) developing an increased understanding of safety-related information that can be obtained from tank headspace sampling.

Safety Issues

The characterization approach for the safety issues continues to evolve as the parameters affecting safe storage and their relationship are better understood. In general, characterization demands are lessened as safety issues become better understood. This section reviews the current safety issues to ensure safe storage and examines the direction of future efforts.

The high-level waste (HLW) tank subcriticality safety assessment concluded that the waste in the Hanford Site waste tanks is in a form that is favorable to maintaining a large margin of subcriticality because of the small quantities of fissile material and the large amounts of neutron-absorbing materials.

The Characterization Program will continue to provide appropriate confirmatory sample data (e.g., fissile material, absorber content, and alkalinity information) as waste samples are obtained for other reasons.

High-heat tanks have been identified through temperature monitoring coupled with thermal analyses. However, only one tank, tank 241-C-106, has demonstrated any substantial high-heat load. This tank is scheduled for retrieval in late

1996. In the meantime, a chiller is being procured for this tank to mitigate potential risk that may be associated with leaks that might result from accelerated corrosion because of the increased temperature.

Waste tank structural integrity evaluations are being completed for all waste tanks. Structural and seismic evaluations are being completed, and the tank life expectancy is being determined for each tank.

Flammable Gases. Flammable gas species (mainly hydrogen and ammonia) are produced at low rates by radiochemical and thermochemical degradation reactions in waste. Vapor from organic solvents may also contribute to headspace flammability. While a mixture of gases may contain flammable constituents, a flammability hazard exists only if a minimum flammability concentration can be retained within the tank headspace (i.e., enough to exceed the minimum fuel concentration known as the lower flammability limit [LFL]). Otherwise, the gases will be dissipated to the atmosphere at concentrations too low to represent a flammability hazard.

For a flammable gas to ignite and burn, it must be mixed with an oxidizer (usually oxygen) and be provided sufficient energy to initiate the chemical reactions. A sufficiently dilute mixture of flammable gas (i.e., a concentration below the LFL) and oxidizer will not burn. The National Fire Protection Association recommends that processes be controlled so that flammable gas concentrations are less than 25 percent of the LFL. DOE requires that Hanford Site waste tanks be operated within National Fire Protection Association guidelines; therefore, management efforts must ensure that flammable gas levels are maintained below 25 percent of the LFL.

The flammable gas hazard can be classified according to the mode by which the flammable gases are released from the waste. For a steady-state gas release, gases are released at approximately the rate at which they are formed, and the concern is an accumulation of flammable gases in the tank headspace (i.e., a steady-state flammability hazard). For a limited number of tanks, gases are released episodically at comparatively high rates. For these episodic releases, flammable gas concentrations could and have exceeded 25 percent of the LFL for brief time periods. The LFL has been exceeded several times by tank 241-SY-101 (more than 100 percent of the LFL has been attained on occasion) and at least once by tank 241-AN-105. Forty-seven Hanford Site waste tanks are on a flammable gas Watchlist because the waste in these tanks is believed to have the potential to retain hydrogen gas until appreciable quantities are released. Monitors have been installed on these tanks and access controls have been imposed to minimize the potential hazard.

<u>Steady-State Release of Flammable Gases</u>. All double-shell tanks (DSTs) are actively ventilated, and air exchange is rapid enough (except during an episodic release) to keep steady-state bulk hydrogen concentrations in the headspace well below 25 percent of the LFL. However, most single-shell tanks (SSTs) are passively ventilated and only exchange air with the environment by relatively slow barometric pressure changes and instrument air purges. Therefore, potential accumulation of flammable gases in the headspace and risers of all SSTs has been explored.

Preliminary studies have examined the accumulation of flammable gases in the headspace and risers of SSTs that are not on the flammable gas Watchlist. A more detailed study on flammable gas accumulation is currently being developed. However, calculations performed thus far show that gas production and release rates from thermochemical and radiochemical processes are modest and that passive ventilation alone will keep the headspace well below 25 percent of the LFL. The contribution to the flammable gas mixture from organic solvent vapor is low because the bulk of organic solvent remaining in any tank would likely have a low vapor pressure. Sampling data from tank 241-C-103, which contains a floating organic layer, support this conclusion. Vapors from the organic solvent amount to less than 5 percent of the LFL.

<u>Episodic Release of Flammable Gases</u>. The ability of waste to retain large amounts of gas depends on its physical properties and chemical/radiological composition. The waste retains gases that increase the waste volume (slurry growth) until the gases escape. Slurry gas is only present in tank headspace at high concentrations when it is released by the waste; therefore, the most direct way to characterize gas may be to sample the waste directly.

The amount of gas retained in the waste will be estimated from analyzing the tank operational data. Tank monitoring data include changes in surface level (resulting from gas release events and changes in atmospheric pressure) and axial waste temperature profiles. New, more accurate level gages and instrument trees (that measure temperature) are being installed in Hanford Site waste tanks. In addition, standard hydrogen monitoring systems (SHMS) are also being installed on all flammable gas Watchlist tanks.

Near-Term Characterization of Flammable Gas. Sampling and/or continuous monitoring is being used to confirm that flammable gas does not accumulate in the SSTs. Headspace sampling results from 30 SSTs (none of which are on the flammable gas Watchlist) indicate that flammability in the headspace and risers is well below 25 percent of the LFL. Headspace sampling of passively ventilated SSTs for flammable gases will continue until all are sampled. None of these tanks are expected to contain steady-state flammable gas concentrations above 25 percent of the LFL. However, if concentrations greater than 25 percent of the LFL are measured for non-Watchlist tanks, then these tanks would become candidates for continuous gas monitoring and potential mitigation.

The headspace of tanks that are suspected of having waste that releases flammable gases episodically will be continuously monitored for flammable gases. SHMS have been designed, built, and installed on all flammable gas Watchlist tanks. SHMS contain instrumentation that support an online hydrogen detector and a gas grab sampler.

Future Characterization of Flammable Gases. Two techniques that are being developed to directly characterize waste for retained gas are 1) a void meter to measure the volume fraction of the gas phase in the waste, and 2) a retained gas sampling system to extract a waste sample from a tank so that the waste can be analyzed (gas can exist as a distinct phase in the waste, and it can also be absorbed on solid or dissolved in aqueous liquid phases). In the near future ammonia monitoring capability will be added to the SHMS. Another system is being developed for in situ measurement of physical properties (density, viscosity, shear strength) that are critical to evaluating stored gas. Development of these systems is underway.

Noxious Vapors

Several health and safety issues are related to noxious vapors that may be present in some of the HLW tanks at the Hanford Site. A tank-by-tank sampling approach is being pursued to resolve headspace issues dealing with flammability and noxious vapors. Vapor sampling will be conducted on all tanks in the Tank Farm Complex.

Modeling and vapor data from tank 241-C-103 indicate that the tank head space is well mixed except during an episodic gas release. To verify that the headspace is well mixed, additional headspace sampling at different vertical and horizontal locations will be conducted in selected tanks.

If any compounds are detected inside a tank dome with toxicological properties that exceed their respective trigger points, Westinghouse Hanford Company (WHC) Industrial Hygiene is advised that gases with toxicological concern are present in the tank headspace. The trigger point has been defined as 50 percent of the appropriate Consensus Exposure Standard (CES) concentration for all analyses of interest. A CES, which is generally defined as the most stringent of known regulatory or recommended toxicological values for the occupational setting, includes the threshold limit value, permissible exposure limit, recommended exposure limit, and biological exposure limit.

The data required to assess toxicity include 1) identifying chemical compounds in the tank headspace of concern for worker health and safety or toxicological importance; 2) estimating the concentrations of these toxicologically substantial compounds in the headspace; and 3) understanding the toxicological effects of these compounds and the CES for each constituent of concern.

Organic Solvents

Various separation processes involving organic solvents have been used at the Hanford Site. These organic solvents were inadvertently and/or purposely sent to the underground storage tanks, and subsequent waste transfer operations distributed organic solvents among several of the 177 HLW tanks. The potential hazards associated with organic solvent are 1) contributing to headspace flammability (as discussed previously); 2) igniting an organic solvent pool; and 3) igniting an organic solvent that is entrained in waste solids.

Currently, one tank (241-C-103) is known to contain an organic solvent pool. Additional tanks that may contain an organic solvent pool will be identified through continued vapor sampling of the tank headspace. Analyses have shown that solvent pool fires are difficult to initiate. Waste that may contain entrained organic solvent will also be identified through vapor sampling of the tank headspace. These analyses have been integrated into the noxious vapor sampling campaign. If vapor sampling suggests the presence of organic solvent, liquid grab samples and/or near-surface samples will be obtained to better quantify the potential for an organic solvent fire.

Fuel-Nitrate (Condensed-Phase) Reactions

Organic complexants and ferrocyanide were sent to the tanks. These compounds have the potential to act as a fuel when combined with an oxidizer. Nitrate salts have also precipitated in the tanks and are potential oxidizer sources. For the organic complexant (nonvolatile materials) and ferrocyanide safety issues, the approach to safety characterization is based on the fact that propagating reactions cannot occur if either the fuel, oxidizer, or potential initiators (e.g., temperature or energy) are controlled. Because specific limits of fuel, oxidizer, and initiators must be satisfied for a propagating chemical reaction to occur, waste can be stored safely if the conditions for the reaction are not possible. Therefore, the approach for obtaining characterization information is to obtain data that would confirm that one of the conditions of fuel or oxidizer is not present in sufficient quantities or that initiators are absent or can be controlled.

An important parameter in controlling propagating reactions is an inhibitor such as moisture. In sufficient quantity, moisture will prevent propagating reactions by 1) behaving as an inert diluent (lowering the effective fuel concentration); 2) preventing initiation of a propagating reaction (the energy from most credible initiators would be absorbed by the sensible and latent heat of the moisture before the waste reached the critical initiation temperature); and 3) providing a large heat sink that inhibits propagation (for a reaction to propagate, enough energy must be supplied to overcome the sensible and latent heat of the moisture present).

Fuel and Moisture Criteria - Experiments have shown that moisture can prevent condensed-phase propagating reactions. Tube propagation tests on waste simulants have shown that propagating reactions cannot occur in waste simulants containing more than 20 weight percent moisture. Sufficient moisture content can ensure that a propagating reaction will not occur, regardless of the fuel-oxidizer concentration. For example, if adequate moisture can be confirmed through monitoring, analysis, or sampling, then it can be concluded that condensed-phase exothermic reactions will not occur, thus ensuring interim safety waste storage.

The minimum required fuel concentration has been determined using a contact temperature ignition model. A necessary (but not sufficient) condition for a condensed-phased propagating chemical reaction is that the fuel concentration be greater than 4.5 weight percent total organic carbon (TOC), based on sodium acetate as fuel, or 1,200 joule/gram (J/g) on an energy equivalent basis. For fuel concentrations between 1,200 and 2,100 J/g, the waste moisture content required to prevent a propagating reaction varies linearly from 0 to 20 weight percent. Above 20 weight percent moisture, the fuel-moisture linear relationship no longer holds because the mixture become a continuous liquid phase, effectively preventing propagating reactions. Note that the TOC criteria depends on the chemical concentration of the waste. Table E.1.0.2 summarizes the criteria for safe storage.

Table E.1.0.2 Safe Storage Criteria

Parameters Affecting Fuel Concentration - Waste tank operations have affected fuel concentration in the tanks. Experiments on waste simulants have shown that the high-energy organic complexants (i.e., the organic salts that could support a propagating reaction) are highly soluble in the tank supernatant solutions. Subsequent pumping of the tank liquid might have removed most of the organic complexant fuels.

Ferrocyanide waste stored in Hanford Site tanks has been exposed to caustic solutions and radiation for nearly 40 years. Long-term degradation (aging) of ferrocyanide is known to have occurred through chemical and radiolytic processes in the waste. Analyses of core samples taken from six of the 18 ferrocyanide tanks reveal fuel values about an order of magnitude less than the original flowsheet concentrations. These remaining fuel values are well below the concentration of concern. Experimental work at Georgia Tech and Pacific Northwest National Laboratory (PNL) has demonstrated that complexants and other organics degrade under radiation and/or chemical oxidation conditions found in tanks. In addition, analysis of the original tank 241-SY-101 core sample complexant waste demonstrated extensive chemical degradation products.

Near-Term Characterization of the Condensed Phase - Current characterization efforts are focused on testing tank waste samples to confirm that the criteria shown in Table E.1.0.2 are conservative for actual waste. That is, if the waste meets the energy (fuel value), TOC, or moisture criterion, then the waste will not support a propagating reaction. Waste from selected tanks will be tested for reaction propagation in the same type of adiabatic calorimeter (the reactive system screening tool) that was used to develop the criteria.

Near-term sampling efforts are also focused on confirming degradation of ferrocyanide and organic complexant waste. Full-depth core samples from ferrocyanide tanks will be analyzed for fuel, nickel (a signature analyte of the sodium nickel ferrocyanide scavenging campaign), and total cyanide to confirm ferrocyanide aging. Full-depth core samples for organic complexant tanks will be analyzed for organic species to confirm that organic complexants have degraded to less energetic species.

In addition, liquid and solid samples from organic complexant tanks will be analyzed to confirm the laboratory demonstration that high-energy organic complexants are soluble.

Reaction Ignition

Credible Ignition Sources - If the waste has a sufficiently high fuel and low moisture content, a propagating reaction could be initiated if an energy source raised the temperature of the waste to the reaction initiation temperature. The potential for tank farm equipment and operations to initiate propagating reactions has been evaluated and is summarized in Table E.1.0.3. In this evaluation, all credible initiators would be located near the waste surface, with the exception of rotary-core drilling incidents and lightning.

Table E.1.0.3 Summary of Operation Evaluation

Although rotary-core drilling incidents and lightning strikes cannot be deemed incredible initiating events, the risk can be mitigated with controls. The rotary-core driller is designed with safety interlocks that limit increases in drill bit temperature. Ignition from lightning strikes can be prevented by appropriate grounding. The need to further ground the SSTs is being studied because of their unique construction.

The TWRS Safety Program is currently establishing the requirements for analytical data to confirm the models used in the safety analysis and the conservatism of the source-term. This additional characterization information will provide the basis for conforming, adjusting, or eliminating controls at Hanford Site waste tanks to ensure adequate protection of the workers, public, and the environment.

Criticality

Based on new information available to DOE, regarding nuclear criticality safety concerns during retrieval, transfer, and storage actions since the issuance of the Final Safe Interim Storage EIS, DOE has decided to defer a decision on the construction and operation of a retrieval system in tank 241-SY-102. Through an ongoing safety evaluation process, DOE recently revisited its operational assumptions regarding the potential for the occurrence of a nuclear criticality event during waste storage and transfers. Changes to the Tank Farm Authorization Basis for Criticality that were approved in September 1995 were rescinded by DOE in October 1995, pending the outcome of a criticality safety evaluation process outlined for the Defense Nuclear Facility Safety Board on November 8, 1995. Until these criticality safety evaluations are completed, the Hanford Site will operate under the historic limits, which maintain reasonable insurance of subcritical conditions during tank farm storage and transfer operations. Of the actions evaluated in the Final Safe Interim Storage EIS, only the retrieval of solids from tank 241-SY-102 was affected by the technical uncertainties regarding criticality. Based on the quantities of plutonium in tank 241-SY-102 sludge, retrieval of the solids falls within the scope of the criticality safety issues that will be evaluated over the next few months. As a result, a decision on retrieval of solids from tank 241-SY-102 was deferred in the Safe Interim Storage EIS Record of Decision. Also, pending the outcome of the technical initiative to resolve the tank waste criticality safety issue, transfers of waste (primarily saltwell liquid) through tank 241-SY-102 will be limited to noncomplexed waste. Tank 241-SY-101 mixer pump operations, interim operations of the existing cross-site transfer system, operation of the replacement cross-site transfer system, saltwell liquid retrievals, and 200 West Area facility waste generation all would occur within the applicable criticality limits and would be subcritical.

The remainder of this document analyzes potential accidents and the related consequences that could occur from implementing the alternatives addressed in this EIS.

Risk from Remediation Accidents

Accidents are unplanned events or a sequence of events that cause undesirable consequences. The risk associated with an accident is defined as the product of the probability of an accident occurring and the consequences of the accident. This includes nonradiological injuries, illnesses, and fatalities from construction, operations, or transportation accidents. Risk is also defined as the probability or the number of latent cancer fatalities (LCFs) from radiological or toxicological releases, given the occurrence and consequences of an accident. This analysis considers both types of risk.

An analysis was performed to determine the nonradiological and nontoxicological risks from construction, operations, and transportation. These are called occupational risks and include personal injuries, illnesses, and fatalities common to the work place such as falls, cuts, and operator-machine impacts.

An analysis was also performed to determine the potential for radiological and toxicological impacts. The results of the analyses are summarized in the following subsections. More detailed information concerning the methodology, supporting data, and assumptions for the basis of the analysis is contained in this appendix.

The alternatives, as described in Volume Two, Appendix B, include the following:

Tank Waste

- No Action alternative
- Long-Term Management alternative
- In Situ Fill and Cap alternative
- In Situ Vitrification alternative
- Ex Situ Intermediate Separations alternative
- Ex Situ No Separations alternative
- Ex Situ Extensive Separations alternative
- Ex Situ/In Situ Combination 1 and 2 alternatives
- Phased Implementation

Cesium (Cs) and Strontium (Sr) Capsules

- No Action alternative
- Onsite Disposal alternative
- Overpack and Ship alternative
- Vitrify with Tank Waste alternative

E.1.1 RADIOLOGICAL LATENT CANCER FATALITY RISK AND CHEMICAL EXPOSURE

The methodology used to identify and quantify the radiological cancer risks, chemical exposures, occupational injuries, illnesses and fatalities, and transportation risks from postulated accidents are discussed in this section. The radiological LCF risk and chemical exposure to humans from accidents was performed using the following steps:

- Identify the spectrum of potential accidents associated with each alternative (Section E.1.1.1, Accident Identification);
- Select the dominant (highest potential risk) accidents for risk analysis (Section E.1.1.2, Accident Scenario Selection);
- Determine the radiological and chemical inventories potentially released in the accidents (Section E.1.1.3,

Source-term and Direct Exposure);
- Calculate the probability of occurrence of the potential accident (Section E.1.1.4, Probabilities);
- Determine the location of the worker, noninvolved worker, and general public (receptors) relative to the point of release of the waste material (Section E.1.1.5, Receptor Locations);
- Determine the radiological dose and chemical exposure to the worker, noninvolved worker, and general public at the location of the receptor (Section E.1.1.6, Radiological Dose and Chemical Exposure Assessment); and
- Calculate the LCF risk and compare the chemical exposure to concentration limits (Section E.1.1.7, Risk Development).

The following subsections discuss these steps in detail.

E.1.1.1 Accident Identification

A hazard is an inherent physical or chemical characteristic that has the potential for causing harm. The potential release of high-level radioactive waste to the environment from the tank farms and processing facilities that are included in the various alternatives is of concern to DOE, Hanford Site workers, and the public. Initiating events that could result in such a release include natural phenomena, human error, component failure, and spontaneous reactions.

Accidents are unplanned events or a sequence of events that result in undesirable consequences. The first step in the analysis was to identify the spectrum of potential accidents associated with construction, transportation, and operation activities involved in each TWRS EIS alternative. Construction activities include potential occupational accidents. Transportation activities include potential radiological, toxicological, and occupational accidents. Operation activities include potential radiological, toxicological, and occupational accidents.

The compilation of potential accident scenarios for tank farms, waste transfer facilities, pretreatment facilities, and processing facilities for each alternative is contained in the accident data package (Shire et al. 1995). This accident data package was prepared specifically to support the TWRS EIS. The spectrum of potential accidents identified in the data package are summarized in Table E.1.1.1.

Table E.1.1.1 Summary of Potential Tank Waste Accidents

Each alternative was divided into six components as applicable: continued operations (C), retrieval (R), pretreatment (separations of HLW from low-activity waste [LAW]) (P), treatment or immobilization (I), transportation (T), and disposal (D). A determination was then made whether each potential accident could occur during each component for each alternative. Not all alternatives involve every component. For example, there is no treatment component for the No Action tank waste alternative. In addition, not every potential accident can occur in a particular component for every alternative. For instance a dropped canister filled with vitrified HLW could only happen during treatment in the Ex Situ Vitrification alternatives. In Table E.1.1.1, an "x" indicates that the accident is applicable to the component for the identified alternative.

Each potential accident in Table E.1.1.1 is coded with a multi-digit number corresponding to the subsection in which it was found in the accident data package (Shire et al. 1995 and Jacobs 1996). A more detailed description of these accidents is provided in the referenced sections in the data package.

E.1.1.2 Accident Scenario Selection

After the potential accidents were identified, accidents with highest risks for each general waste-handling activity were screened and analyzed in further detail.

Screening for the highest risk accidents involved listing all the potential accidents from Table E.1.1.1 on an accident screening table. Table E.1.1.2 is an example of a screening table. The table identifies the broad range of potential accidents and assigns calculated or estimated risk (frequency of the event times the consequences) of each accident. The potential hazards were grouped according to the mode of operation and subdivided further according to the activity within this mode. The risk shown in the last column is the product of the annual frequency of the event happening and the severity(consequences) of the accident. The values used in the annual frequency and severity columns are qualitative as defined in Tables E.1.1.3 and E.1.1.4. For the frequency of the event, factor values of 4 (anticipated); 3 (unlikely); 2 (extremely unlikely); and 1 (beyond design basis) were assigned. For the severity of the events, factor values of 4 (high); 3 (moderate); 2 (low); and 1 (no) were assigned. The factor values used for the frequency of the event and the severity of the event are numbers used only for the purpose of screening. Where the risk values for more than one event in the same category are the same, the rationale for choosing the scenario to be evaluated was based on the accident with the highest severity. It should be noted that accident scenarios with the worst radiological consequences would also result in the worst chemical exposures.

Table E.1.1.2 Example Accident Screening Table

Table E.1.1.3 Frequency Category Definition

Table E.1.1.4 Qualitative Accident Severity Levels

Beyond design basis accidents were also analyzed for each alternative. For this analysis, beyond design basis accidents are accidents with a frequency range of 1.0E-06 to 1.0E-07 per year (design basis accidents are greater than 1.0E-06 per year) for operator external accidents or below the Site-specific designated return frequency for natural events. This does not mean that the facilities have been designed to this accident frequency range. Accidents with frequencies less than 1.0E-07 (less than one in10million) per year were not examined because of their extremely low probability of occurrence.

When an alternative has been selected for remediation of the Hanford tank waste, if accidents associated with the alternative exceed the acceptable limits of risk, mitigation measures may be required to reduce the level of risk.

The types of accidents selected for evaluation in the TWRS EIS are consistent with the types of accidents currently being developed for the TWRS Final Safety Analysis Report (FSAR). The FSAR is comprehensive and detailed evaluation of the potential accidents that could occur within TWRS and will be used to establish safe operating methods. The preliminary FSAR is scheduled to be issued in the fall of 1996. Because the accident analyses for the FSAR are at different stages of development and review, they are subject to change at this time. The three worst-case scenarios being developed in the TWRS FSAR that were evaluated as bounding design basis accidents in the TWRS EIS are:

- Spray leak in a valve pit during waste transfer;
- Flammable gas deflagration in a waste storage tank; and
- Organic nitrate fire in a waste storage tank.

The spray leak in a valve pit was identified in the screening analysis as the accident with the highest risk during waste tank transfer for the continued operations component.

The flammable gas deflagration in a waste storage tank was identified as having a higher risk than an organic nitrate fire in a storage waste tank during continued operations; therefore, the flammable gas deflagration was selected for further evaluation to determine the radiological and toxicological risks.

The beyond design basis accident evaluated in the TWRS EIS is a seismic event resulting in the collapse of a SST dome. The TWRS FSAR is currently developing a beyond design basis earthquake scenario that would result in tank failure.

The consequences presented in the Final EIS are based on National Environmental Policies Act (NEPA) guidance that calls for an integrated risk assessment based on a "reasonably foreseeable" accidents that could occur over the lifetime of the operation. The consequences presented in the FSAR result from worst-case scenarios based on extreme parameters. The worst-case scenarios are used to determine the hazard classification and the safety classification and are not considered to be "reasonably foreseeable" scenarios and therefore inappropriate for an EIS. To develop an integrated risk for the EIS based on the worst-case scenarios would result in unrealistic and undefendable risk values.

E.1.1.3 Source-term and Direct Exposure

For this analysis the source-term is the respirable fraction of inventory from which the receptor dose is calculated. It is based on the inventory that could potentially be released to the environment from an accident, referred to as material at risk (MAR), multiplied by the applicable reduction factors listed in the following text. Use of the reduction factors is dependent on the nature of the accident (i.e., energy of accident at impact, waste form, and effectiveness of mitigating barriers such as high-efficiency particulate air [HEPA] filter).

Damage ratio (DR) - The fraction of the MAR impacted by the event.

Airborne release fraction (ARF) - The fraction of released material made airborne by the event at the point of origin.

Airborne release rate (ARR) - The fractional ARR of material resulting from the accident at the point of origin. ARR is converted to ARF by integrating over the time available for release.

Leak path factor (LPF) - The fraction that escapes the confinement boundary by design, natural causes, or degradation caused by the event.

Respirable fraction (RF) - The fraction of airborne droplets or particulate matter with individual particle aerodynamic equivalent diameter less than or equal to 10 micrometers (m) (3.9 E-04 inches [in.]).

Exposure also may result from direct exposure to radiation. Direct exposure is the direct gamma radiation dose rate to a receptor.

It should be noted that the ingestion and groundshine pathways were not included for remediation accidents because of the corrective action that would be taken by DOE to remediate the release from the accident. Corrective actions would be taken that would include 1) restricting access to the impacted area; 2) evacuating offsite populations within the area of impact; and 3) remediating contaminant deposition to levels that ensure protection of human health before access to the area would be allowed.

Under all accident scenarios, most of the deposition would occur near the tank farms and extend at diminishing levels to the Site boundary in the direction of the prevailing wind at the time of the accident. Deposition would also occur at much lower levels offsite, with the highest levels closest to the Site boundary and diminishing levels out to a 80 kilometers (km) (50-mile [mi]) radius of the Site where no depositions at levels that would impact human health or the environment would occur. In addition to the direct impacts to human health resulting from inhalation, if an accident were to occur there would be additional impacts that would potentially occur based on the magnitude of the accident. These impacts could include:

- Restrictions on access to sites sacred to Tribal Nations impacted by depositions on the Hanford Site during remediation of the depositions;
- Temporary disturbance to ecological, biological, and cultural resources impacted by depositions and the resulting remediation of the depositions; and
- Economic impacts associated with the cost of the remediation of depositions and the dislocation of populations within the area of impact.

All of the accident scenarios during remediation have small offsite consequences or the probability of the event is extremely unlikely. Therefore, a detailed analysis of environmental, socioeconomic, and cultural impacts from these accidents, in accordance with NEPA guidance (DOE 1993d), have not been performed. However, a relative comparison among the alternatives of the impacts of these potential accidents is possible based on the human health impacts addressed previously. In most cases, the greater the impact to human health, the greater the environmental, socioeconomic, and cultural impact that would result from the accident.

Post-remediation accidents that take place after the 100-year institutional control period assume no corrective action and include the added risk from groundshine, ingestion, and deposition.

E.1.1.3.1 Inventory

The tank waste inventory for the SSTs, DSTs, and MUSTs is presented in Appendix A, Section A.2.1, Tables A.2.1.1, A.2.1.2, and A.2.1.3 of this EIS. The Cs and Sr capsule inventory at the Waste Encapsulation Storage Facility (WESF) are presented in Table A.2.2.1. However, for developing tank farm accidents, a 100 percent inventory bounding composite was developed. This composite incorporates historical tank contents estimates, the results from prior individual tank analyses, and the results of recent tank characterization programs (Shire et al. 1995 and Jacobs 1996). This composite was developed because engineering information was not sufficiently mature to determine which tanks would have their inventory mixed during retrieval and transfer. This could be thought of as a single tank containing the highest activity concentration for each nuclide found in the sample data. This maximum sample activity composite grouping means the highest radioactivity concentration for each radionuclide is combined to define a hypothetical "highest concentration" inventory used to bound the accidents. For process facility accidents a 90 percent composite was assumed.

A less conservative approach was also used to estimate the inventory of radioactive materials contained in the fuel from the single-pass reactors and N Reactor and sent to the tank farms. Total radionuclide inventories were calculated based on the complete operating history of all of the Hanford Site production reactors. Reduction factors were then applied to the total inventories to account for plutonium (Pu) and uranium (U) extracted from the waste sent to the tanks. Reduction factors also were applied to Cs and Sr, which also were extracted from the waste. The 11 radionuclides that contribute to over 99 percent of the total dose as reported in the supporting document for developing the unit liter doses (ULDs) (WHC 1996c) are shown in Table E.1.1.5 with the total activity of each nuclide.

Table E.1.1.5 Tank Inventory Based On Reactor Products

Because the tank waste inventory has not yet been well characterized, bounding and nominal radiological and toxicological consequences are presented in the analysis to provide a risk range.

E.1.1.4 Probabilities

The probabilities of radiological and toxicological accidents occurring were taken from the accident data package (Shire et al. 1995 and Jacobs 1996). The accident probability data package was prepared specifically to support the TWRS EIS. The accident initiator frequencies were established using currently accepted sources of occurrence frequency such as natural phenomena statistics for the Hanford Site, recent analysis of the initiators, or industry-accepted frequencies.

The probabilities have conservatively not taken into account 1) the frequency of time the wind blows in the direction of the presumed receptor location (the wind is always assumed to blow towards the receptor); 2) the likelihood the receptor would be at the presumed receptor location for the duration of the plume passage; 3) the likelihood that the source-term (composite inventory) would be released. It is assumed that the composite inventory would always be released; and 4) emergency planning and evacuation programs are in place at the Hanford Site to mitigate potential consequences resulting from an accident. In the event of an accident, the Emergency Control Center is responsible for determining the correct plan of action in accordance with the Emergency Management Procedures (WHC 1996a). For example, if the appropriate plan of action is to take cover, individuals are notified by announcements over the public address system to go inside building(s). The ventilation system is turned off to prevent unfiltered air, with contaminants, from entering the buildings. If the appropriate plan of action is to evacuate the Site, an orderly evacuation with designated meeting places is conducted. It has been demonstrated that evacuation can be conducted in less than an hour (Sutton 1996).

Accidents with annual frequencies greater than 1.0E-06 were considered to be within design basis accidents. Beyond design basis accidents have an annual frequency range from 1.0E-06 to 1.0E-07. Accidents with annual frequencies less than 1.0E-07 were not examined.

E.1.1.5 Receptor Locations

The radiological dose to a receptor depends on the location of the receptor relative to the point of release of the radioactive material. Doses for a maximally-exposed individual (MEI) and population dose were computed for each receptor (worker, noninvolved worker, and general public). Workers are those involved in the proposed action and are in the work place performing work at the facility. Noninvolved workers are onsite workers but not involved in the proposed action. The general public are those located off the Hanford Site. The MEI for each of these three receptor categories is a single individual that is assumed to receive the highest exposure in the category. The location of each receptor is discussed in the following text.

Worker Population and Maximally-Exposed Individual Worker - The worker population and MEI worker are those individuals directly involved in implementing the alternatives. They are assumed to be in the center of a 10 m (33.0 foot [ft]) radius hemisphere where the airborne released material has spread instantaneously and uniformly and would expose a typical size crew of 10 people.

Noninvolved Worker Population - The noninvolved worker population was based on the Site employment and was assumed to extend from 100m (330 ft) out to the Hanford Site boundary. The Hanford Site specific population was obtained from the Hanford Site phone directory and increased by 10 percent to account for uncertainties. No reduction was applied for multiple work shifts or absences. All employees were assumed to be present. For accidents at the tank farms, the noninvolved worker population would be 1,835. For accidents at the vitrification facilities, the population would be 5,500.

Maximally-Exposed Individual Noninvolved Worker - The MEI noninvolved worker was assumed to be located at 100m (330 ft) from the release point in the direction that produces the highest dose. This distance was used rather than the actual nearest building location, because new construction or movement of trailers and relocateable buildings can change the actual nearest building locations.

General Public Population - The offsite population distribution from the Hanford Site boundary to a distance of 80 km (50 mi) was taken from the GENII computer code (Napier et al. 1988). The offsite population would be 114,734.

Maximally-Exposed Individual General Public - The MEI general public was assumed to be located at the Hanford Site boundary (Volume 1, Figure 1.0.1) in the direction that produces the highest dose. An adjusted Site boundary that excludes areas likely to be released by DOE in the near future was used in the analysis. The Site boundary for the EIS was defined as follows:

- N. Columbia River - 0.4 km (0.25 mi) south of the south river bank.
- E. Columbia River - 0.4 km (0.25 mi) west of the west river bank.
- S. A line running west from the Columbia River, just north of the Washington Public Power Supply System (Supply System) leased area, through the Wye Barricade to Highway 240.
- W. Highway 240 and Highway 24.

E.1.1.6 Radiological Dose and Chemical Exposure Assessment

The computer code GXQ was used to calculate the dispersion of potential radiological releases into the atmosphere referred to as the atmospheric dispersion coefficient (Chi/Q). GXQ has been verified and benchmarked against the GENII computer code. The calculations use the most recent available meteorological joint frequency data based on the nine-year (1983 through 1991) average data from the Hanford Site meteorology tower in the 200 Area (Schreckhise 1993). The method for computing Chi/Q is based on Nuclear Regulatory Commission (NRC) Regulatory Guide 1.145 (NRC 1982). All accident-induced releases were assumed to be ground level releases, and plume meander was factored into the GXQ model. Plume rise, building wake, and dry deposition were not used. The receptor was assumed to be located at the plume centerline (i.e., at the location of peak concentration). For the bounding scenarios, the greater of the 99.5 percent maximum sector or 95 percent overall Site Chi/Q values were used.

Doses for atmospheric releases were computed with the GENII code, which has been verified and validated. The doses from radioactivity deposited inside the body were computed using weighting factors for various body organs and the results summed to calculate a committed effective dose equivalent (CEDE). The computer code was used to calculate the inhalation dose for a 70-year dose commitment period.

The radiological dose [D (Sv)] for the noninvolved worker and general public receptors were calculated using the straight-line Gaussian dispersion model as shown in the following equation:

$$D\ (Sv) = [Q\ (L)] \cdot [Chi/Q\ (s/m^3)] \cdot [R\ (m^3/s)] \cdot [ULD\ (Sv/L)]$$

Where:

Q = Liters of respirable waste released from the accident

Chi/Q = Time integrated atmospheric dispersion coefficient calculated by GXQ code

R = Typical acute breathing rate of 3.3E-04 cubic meter per second (m^3/s) (1.2E-02 cubic feet per second (ft^3/s) (ICRP 1975)

ULD = CEDE per unit liter inhaled.

The liters of respirable waste released (Q) is the source-term as defined in Section E.1.1.3. The Chi/Q is generated by the GXQ computer code (Section E.1.1.5.3). The breathing rate (R) is the typical acute (light activity) breathing rate. The ULD was generated by the GENII computer code for composite source-terms and the values are given in terms of CEDE per unit liter of waste inhaled at the receptor location.

The radiological dose [D (Sv)] for the worker receptor was calculated using the following equation:

$$D\ (Sv) = [Q\ (L)] \cdot [BR\ (m^3/s)] \cdot [t\ (s)] \cdot [2/3\ ?\ r^3]^{-1} \cdot [ULD\ (Sv/L)]$$

Where:

Q = Liters of respirable tank waste released

t = Duration of worker exposure

BR = Typical acute breathing rate, 3.3E-04 m^3/s (1.2E-02 ft^3/s)

r = Assumed 10 m (33ft) radius from point of release for distribution of source activity

ULD = CEDE per unit liter inhaled.

Peak concentrations, C (mg/m^3), for a continuous release of solid or liquid chemical materials were calculated using the following equation:

$$C\ (mg/m^3) = [Q\ (mg/s)] \cdot [Chi/Q\ (s/m^3)]$$

Where:

Q = Chemical material release rate

Chi/Q = Continuous release atmospheric dispersion coefficient.

The volume of respirable material released (Q) is the source-term and the Chi/Q was generated by GXQ computer code.

For instantaneous or short duration releases of chemicals, the maximum puff Chi/Q was used. The following equation was used to calculate the peak concentration:

$$C\ (mg/m^3) = Q\ (mg) \cdot Chi/Q\ (1/m^3)$$

Where:

Q = Toxic material released

Chi/Q = Puff release atmospheric dispersion coefficient.

E.1.1.7 Risk Development

Radiological risk. The likelihood that a dose of radiation would result in a fatal cancer at some future time is known as LCF and is calculated by multiplying the calculated dose (radiation effective man [rem]) by a risk factor, or dose-to-risk conversion factors. Conversion factors are predictions of health effects from radiation exposure. The dose-to-risk conversion factors used for estimating cancer deaths from low doses of radiological exposure and from high doses were taken from Recommendations of the International Commissions on Radiological Protection (ICRP 1991). They are summarized as follows:

- Onsite (worker and noninvolved worker) - 4.0E-04 LCF/person-rem or 400 cancer fatalities per million person-rem for low doses (less than 20 rem) and 8.0E-04 LCF/rem or 800 cancer fatalities for million person-rem for doses greater or equal to 20 rem.
- Offsite (general public) - 5.0E-04 LCF/person-rem or 500 cancer fatalities per million person rem for low doses (less than 20 rem) and 1.0E-03 LCF/rem or 1,000 cancer fatalities per million person-rem for high doses greater or equal to 20 rem. The difference in the onsite and offsite conversion factors is attributable to the presence of children offsite.

Multiplying the dose by the conversion factor shows the risk only if the accident takes place. Because the probability of the accident also needs to be factored into the evaluation, the radiological LCF risk is the product of the receptor dose, the dose-to-risk conversion factor, and the probability of the accident.

The quantitative estimate for the population receptors is the number of fatal cancers resulting from the radiological exposure. For the MEI receptors it is the probability the individual will die from cancer as a result of the exposure.

Other biological effects may result from radiological exposures. Somatic effects that occur early as a result of receiving a large dose in a short period of time (acute exposure) include vomiting, nausea, and diarrhea from a dose of 25 rem up to 220 rem. Deaths begin to occur beyond 220 rem with up to 100 percent deaths from doses between 500 to 750 rem.

Chemical risk - Potential acute hazards associated with exposure to concentrations of postulated accidental chemical releases were evaluated using a screening-level approach for the MEI worker, MEI noninvolved worker, and the MEI general public. This screening-level assessment involved direct comparison of calculated exposure point concentrations of chemicals to a set of site-specific (i.e., Hanford Site-specific) air concentration screening criteria, known as emergency response planning guidelines (ERPGs).

ERPGs, as developed by the American Industrial Hygiene Association (AIHA), are specific levels of chemical contaminants in air designed to be protective of acute adverse health impacts for the general population. ERPGs are defined in the following text.

ERPG-1 - The maximum airborne concentration below which it is believed that nearly all individuals could be exposed for up to 1 hour without experiencing other than mild transient adverse effects or perceiving a clearly defined objectionable odor.

ERPG-2 - The maximum airborne concentration below which it is believed that nearly all individuals could be exposed for up to 1 hour without experiencing or developing irreversible or other serious health effects or symptoms that could impair their ability to take protective action.

ERPG-3 - The maximum airborne concentration below which it is believed that nearly all individuals could be exposed for up to 1 hour without experiencing or developing life-threatening health effects.

For the accident scenarios evaluated, AIHA ERPGs were used as the primary criteria. For those chemicals lacking published AIHA ERPGs, Hanford Site-specific ERPGs were used as published in the Toxicological Evaluation of

Tank Waste Chemicals, Hanford Environmental Health Foundation (HEHF) Industrial Hygiene Assessments (Dentler 1995). These tank farm-specific ERPGs were developed by HEHF for the purpose of evaluating health hazards associated with chemicals in the tank farms from accidental releases.

Chemicals were subdivided based on acute health impacts into toxic chemicals or corrosive/irritant chemicals. Given the lack of quantitative data and large number of target organs affected by a chemical from acute exposure, chemicals within each group were conservatively assumed to be additive. Cumulative hazards or the Acute Hazard Index for the toxic and corrosive/irritant chemical classes were evaluated as follows:

$$\text{Cumulative Hazard (Acute Hazard Index)} = C_1/E_1 + C_2/E_2 + ... + C_i/E_i$$

Where

C_i = Calculated airborne exposure point concentration for the ith chemical, (mg/m^3)

E_i = The ERPG for the ith chemical (mg/m^3)

Cumulative hazard indices were estimated for each MEI receptor and for each ERPG screening level (e.g., ERPG-1, ERPG-2, and ERPG-3). A cumulative hazard index greater than 1.0 (unity) indicates that the acute hazard guidelines for a mixture of chemicals has been exceeded and the chemical mixture may pose a potential acute health impact.

For accident scenarios involving the waste storage tanks (e.g., mispositioned jumper resulting in spray release, loss of tank ventilation filtration, and dome collapse, and hydrogen deflagration in storage tanks), the upper-bound, maximum receptor population that could be potentially impacted by an ERPG exceedance is:

- 10 workers (involved);
- 335 noninvolved workers at 290 m (950 ft);
- 1,500 noninvolved workers at 1,780 m (5,840 ft) ;
- 1 MEI noninvolved worker at 100m (330 ft); and
- 114,734 general public receptors.

For accident scenarios involving the vitrification plant (e.g., pretreatment line break in ventilated vault and canister of vitrified HLW inadvertently dropped), the upper-bound, maximum population that could be potentially impacted by an ERPG exceedance is:

- 10 workers (involved);
- 1,500 noninvolved workers at 1,050 m (3,340 ft);
- 1,000 noninvolved workers at 20,500 m (12.7 mi);
- 3,000 noninvolved workers at 30,500 m (19.0 mi);
- 1 MEI noninvolved worker at 100m (330 ft); and
- 114,734 general public receptors.

For any of the above receptor populations, a cumulative acute hazard index greater than 1.0 would be expected to result in the following ERPG-specific effects:

- ERPG-1 exceedance could result in mild transient effects such as minor irritation or objectionable odor perception;
- ERPG-2 exceedance could result in reversible adverse effects such as nausea, vomiting or bronchitis; and
- ERPG-3 exceedance could result in lethal exposures for some or all of the exposed population.

A calculated acute hazard index greater than 1.0 for an ERPG level (ERPG exceedance) is conservatively assumed to impact the entire receptor population.

Potential carcinogenic health effects from chemical exposure were not evaluated for these accident scenarios. Exposure to chemicals from accidental releases was assumed to occur only once, with a maximum duration of 24 hours. All of the carcinogenic chemicals have been shown to produce a carcinogenic response only after administering high doses for a lifetime of exposure. None of these carcinogenic chemicals have been shown to produce a carcinogenic response from an acute exposure. Consequently, a single acute dose can not be evaluated using cancer slope factors derived from chronic or lifetime studies.

E.1.2 OCCUPATIONAL INJURIES, ILLNESSES, AND FATALITIES

Total recordable cases, lost workday cases, and fatalities resulting from construction and operations were calculated by the following equations:

Total recordable cases = (occupational incidence rate) · (manpower required to complete the alternative)

Lost workday cases = (occupational incidence rate) · (manpower required to complete the alternative)

Fatalities = (occupational fatality rate) · (manpower required to complete the alternative).

The injuries, illnesses, and fatalities rates used in the analysis are incidence rates taken from the occupational injuries summary report (DOE 1994j). The total recordable case (injuries and illnesses requiring medical care) and lost workday case (an injury or illness resulting in an employee missing work) rates are specific to the Hanford Site from 1988 through 1992. The fatality rate is the average for all DOE sites from 1988 through 1992 (the report does not distinguish between construction fatalities and operation fatalities). These incidence rates are summarized in Table E.1.2.1.

Table E.1.2.1 DOE and Contractor Incidence Rates

E.1.3 TRANSPORTATION FATALITIES AND INJURIES

Truck and Rail Transport Accidents

The rates of transportation accidents are assumed comparable to that of average truck and rail transport in the United States. Unit-risk factors were developed based on statistics compiled by the U.S. Department of Transportation (Rao et al. 1982). These unit-risk factors are summarized in Table E.1.3.1.

Table E.1.3.1 Unit-Risk Factors for Fatalities and Injuries for Truck and Rail

The number of injuries and fatalities was calculated by multiplying the total distance traveled in each population zone by the appropriate risk factors shown in Table E.1.3.1. The distance traveled in each population zone was calculated by applying the fractions of travel from NUREG-0170 (NRC 1977). The values are 5 percent of the travel in urban, 5 percent of the travel in suburban, and 90 percent of the travel in rural areas. For this analysis the Hanford Site (onsite) is considered to be a suburban zone.

Employee Commuting Accidents

To calculate the expected number of injuries and fatalities resulting from vehicle accidents for employees commuting to and from work, the following injury/fatality rates were taken from the 1993 Washington State Highway Accident Report (WSDT 1993):

- 7.14E-07 injuries/km; and
- 8.98E-09 fatalities/km.

There were 18 recorded injuries and no fatalities at the Hanford Site for both 1993 and 1994. The estimated average vehicle distance driven was 3.46E+07 km (2.15E+07 mi). The injury rate for 1993 and 1994 is therefore calculated at 5.20E-07 injuries/km, which is comparable to the Washington State injury rates listed previously.

E.1. 4 UNCERTAINTY

The uncertainties in calculating the radiological doses and the toxicological exposures resulting from operation accidents include the tank inventory concentration and the atmospheric dispersion once the source-term is in the air. To demonstrate these uncertainties, a sample accident scenario is presented in Volume 5, Appendix K.

The accident initiator frequencies were established using currently accepted sources of occurrence frequency such as natural phenomena statistics for the Hanford Site or recent analysis of the initiators from safety assessment reports. The frequency of these accidents is presented as estimates and is provided as an aid in screening accident scenarios. Differences in frequencies are significant only when orders of magnitude are present. An accident scenario with a frequency of 1E-06 and one with a frequency of 5E-05 should not be considered significantly different in frequency.

The nonradiological injuries and fatalities resulting from construction and operation accidents were based on incidence rates taken from the occupational injuries summary report (DOE 1994j). The transportation injuries and fatalities from trucks and train were based on incidence rates taken from statistics compiled by the U.S. Department of Transportation (Rao et al. 1982). Injuries and fatalities resulting from employee vehicle accidents were based on incidence rates taken from the Washington State Highway Accident Report (WSDT 1993). Because these are widely accepted incidence rates, there was no attempt to evaluate the uncertainties.

E.2.0 NO ACTION ALTERNATIVE (TANK WASTE)

This section analyzes the risk resulting from potential accidents associated with the No Action alternative. The No Action alternative is to continue the following activities:

- Perform routine management and maintenance activities; and
- Continue pumping and evaporating liquid for 10 years.

This section analyzes the transportation and operation risk associated with this alternative. Because tanks and facilities would not be constructed under this alternative, there would be no risk from construction.

E.2.1 TRANSPORTATION ACCIDENTS

Transportation activities associated with this alternative include employees commuting to work each day.

E.2.1.1 Radiological Cancer Risk

All operations would be conducted within established operating parameters for the tanks and would not involve transporting radioactive materials by container. Therefore, there would be no radiological cancer risk resulting from transportation. Accidents involving the transportation of waste in the transfer lines are discussed in Section E.2.2.

E.2.1.2 Chemical Exposure

Because there would be limited transportation of toxic materials (such as lubricants that are used in continued operations), it is extremely unlikely there would be any accidents resulting in chemical exposures. Therefore, transportation accidents involving chemical exposures were not quantified.

E.2.1.3 Occupational Injuries and Fatalities

Employee Traffic Accidents

Workers and other personnel required to perform the various activities would drive to the Hanford Site in their vehicles. The total person-years to perform the activities was estimated at 1.04E+05 (Jacobs 1996).

Each person was assumed to work 260 days a year. The round-trip distance traveled to work from the Tri-Cities area was estimated at 140 kilometers (km) (87 miles [mi]) with an estimated 1.35 passengers per vehicle (DOE 1994a). The total employee vehicle distance was therefore calculated to be 2.80E+09 km (1.74E+09 mi).

To calculate the expected number of injuries and fatalities resulting from vehicle accidents, the injury/fatality rates discussed in Section E.1.3 were used. The expected number of injuries and fatalities resulting from employee vehicle accidents are calculated as follows:

Injuries = (2.80E+09 km) · (7.1E-07 injuries/km) = 2.00E+03

Fatalities = (2.80E+09 km) · (8.98E-09 fatalities/km) = 2.52E+01

E.2.2 OPERATION ACCIDENTS

The potential exists for accidents resulting from routine operation activities. The routine operations are discussed in

Volume Two, Appendix B.

The dominant accident scenarios analyzed in the following subsections were selected from the Accident Screening Table (Table E.2.2.1). The accidents listed in Table E.2.2.1 were taken from the accidents analysis data package (Shire et al. 1995 and Jacobs 1996). The methodology of screening was previously discussed in Section 1.1.2.

Table E.2.2.1 Accident Screening Table for the No Action Alternative (Tank Waste)

E.2.2.1 Continued Operations Accident - Tank Waste Transfers

Continued operations include transferring liquid waste from the SSTs to an evaporator where the solids and liquid are separated. Types of radiological releases resulting from potential accidents associated with continued operations include sprays, leaks, fires/deflagrations, explosions, and ventilation. From Table E.2.2.1 the credible accident (accidents with a frequency of occurring greater than 1.0E-06 per year) identified as having the highest risk was Accident 4.1.7: "mispositioned jumper in SST double-contained receiver tank pump pit with cover off."

A pressurized-liquid spray release from a mispositioned jumper was postulated to occur in an SST double-contained receiver tank (DCRT) pump pit that services the transfer from DCRT to DST or pumps into or out of a receiver tank. A jumper is a short connection pipe that is used in a jumper pit to route tank waste transfers from one line to another line in sending tank waste to a specific location.

E.2.2.1.1 Scenario and Source-term Development for - Mispositioned Jumper

This analysis was based on the following assumptions:

- A jumper was mispositioned and pinhole leaks develop at both ends of the jumper;
- The pump pressure was 1.43E+06 Pascals (Pa) (207 pounds per square inch [psi]);
- The maximum spray leak from each end was calculated to be 0.027 liters per minute (L/min) 0.007 gallons per minute (gal/min) or 0.054 L/min (0.014 gal/min) total;
- All spray particles were assumed to evaporate to less than 10 m before reaching the ground on their calculated trajectory; therefore, 100 percent of the spray was considered respirable;
- The fine spray is not detectable with installed leak detection devices;
- The pump pit was unintentionally left uncovered;
- The release time was for two shifts or 16 hours (960 min); and
- The source-term consists of 70 percent SST liquids and 30 percent SST solids.

Source-term - Assuming a spray duration of two shifts or 16 hours, the source-term was calculated as follows:

$$(0.054 \text{ L/min}) \cdot (960 \text{ min}) = 52 \text{ L } (14 \text{ gal})$$

E.2.2.1.2 Probability of Mispositioned Jumper

The frequency of a mispositioned jumper in a SST DCRT pump pit with its cover off was calculated to range from 1.1E-02 per year to 8.0E-03 per year (Shire et al. 1995 and Jacobs 1996). For conservatism, the frequency of 1.1E-02 was assumed for calculating risk. Waste transfers would take place for up to 10 years; therefore, the probability of the accident was calculated to be 1.1E-01.

E.2.2.1.3 Radiological Consequence from Mispositioned Jumper

The radiological dose to the receptors from the previous source-term was calculated by the GENII computer code (Napier et al. 1988) using the methodology previously discussed in Section 1.1.6. The results, which were taken from the accident data package (Shire et al. 1995 and Jacobs 1996), are summarized in Table E.2.2.2.

Table E.2.2.2 Dose Consequence from Mispositioned Jumper

E.2.2.1.4 Radiological Cancer Risk from Mispositioned Jumper

The LCF risk is the product of the dose to the receptor measured in rem, the dose to risk conversion factor, and the probability of the event. A dose-to-risk conversion factor of 8.0E-04 LCF per person-rem for the workers, MEI worker, and MEI noninvolved worker was used because the individual doses were greater than 20 rem. Dose-to-risk conversion factors of 4.0E-04 LCF per person-rem for the noninvolved worker and 5.0E-04 LCF per person-rem for the general public were used, because the individual doses were less than 20 rem.

Using the workers as an example, a dose to the workers of 5.9E+02 person-rem would result in an estimated 4.7E-01 latent cancer deaths if the accident were to occur. Factoring in the probability of 1.1E-01 the LCF risk (point estimate) was calculated as follows:

$$(5.9E+02 \text{ rem}) \cdot (1.1E-01) \cdot (8.0 E-04 \text{ LCF/rem}) = 5.2E-02 \text{ LCF}$$

The LCF risks for each receptor are calculated in Table E.2.2.3.

Table E.2.2.3 Latent Cancer Fatality Risk from Mispositioned Jumper

The bounding calculations show all 10 workers would potentially receive a fatal dose from radiation if the accident occurred. Approximately seven noninvolved workers would receive fatal cancers, and two LCFs would be incurred to the general public. The nominal scenario calculations show there would be no LCFs.

E.2.2.1.5 Chemical Consequences of Mispositioned Jumper

The chemical exposure to the receptors from the postulated accident were calculated in Appendix A of the accident data package (Shire et al. 1995 and Jacobs 1996 and Jacobs 1996) and summarized in the exposure column in Tables E.2.2.4 and E.2.2.5 for nominal and bounding toxic effects, and Tables E.2.2.6 and E.2.2.7 for nominal and bounding corrosive/irritant effects, respectively. The tables compare the concentration of the postulated chemical releases to acute exposure criteria (ERPGs) discussed in Section 1.1.7.

Table E.2.2.4 Comparison of Chemical Concentrations to Toxic Concentration Limits for Mispositioned Jumper

Table E.2.2.5 Comparison of Bounding Chemical Concentrations to Toxic Concentration Limits for Mispositioned Jumper

Table E.2.2.6 Comparison of Nominal Chemical Concentrations to Corrosive/Irritant Concentration Limits for Mispositioned Jumper

Table E.2.2.7 Comparison of Bounding Chemical Concentrations to Corrosive/Irritant Concentration Limits for Mispositioned Jumper

Toxic Impact from Chemical Exposure

Under nominal conditions (Table E.2.2.4), the cumulative acute hazard ratios for the MEI worker, MEI noninvolved worker and MEI general public were less than 1.0, indicating that no adverse acute health effects would be expected for these three receptors. Under bounding conditions (Table E.2.2.5), the MEI worker was not evaluated since death would occur from exposure to radionuclides. The cumulative acute hazard ratio for the MEI noninvolved worker was 5.36E+00 for ERPG-2, indicating that reversible acute health effects would be expected. This acute hazard ratio was primarily attributable to mercury (approximately 89 percent of the overall hazard ratio). No adverse acute health effects were predicted for the MEI general public under bounding conditions.

Corrosive/Irritant Impact from Chemical Exposure

Under nominal conditions (Table E.2.2.6), the cumulative acute hazard ratio for the MEI worker was 2.70E+00 for ERPG-3, indicating the potential for irreversible health effects that could be life-threatening. This acute hazard ratio was almost entirely attributable to sodium assumed to be equivalent to sodium hydroxide in corrosive/irritant effects. For the MEI noninvolved worker, the cumulative acute hazard ratio for ERPG-1 was 3.0, indicating that only mild, reversible irritant effects would be expected. No acute health impacts were predicted for the MEI general public under nominal conditions. Under bounding conditions (Table E.2.2.7), the MEI worker was not evaluated since death would occur from exposure to radionuclides. For the MEI noninvolved worker, the cumulative acute hazard ratio for ERPG-1 was 4.36E+00, indicating that only mild reversible irritant effects would be expected. No acute health impacts were predicted for the MEI general public under bounding conditions.

Under both nominal and bounding conditions, the probability of a mispositioned jumper is 1.10E-01.

E.2.2.2 Continued Operations Accident - Waste Storage Tanks

Types of radiological releases resulting from potential accidents associated with unstabalized tank waste are fires, deflagrations, and tank leaks. From Table E.2.2.1 the credible accident identified as having the highest risk was Accident 7.1: "hydrogen deflagration in waste storage tank."

E.2.2.2.1 Scenario and Source-term Development for Hydrogen Deflagration in Waste Storage Tank

Hydrogen could be generated in tank waste, rise into tank headspace, and reach the concentrations necessary for combustion. Ignition would occur in the tank headspace during a 1-hour time period when the gas concentration exceeds the LFL. Turbulence accompanying rapid combustion could suspend waste as aerosols and pressure drive some of the particulate out the ventilation system into the environment.

Source-term - The MAR was assumed to be 5.0E+05 L (1.3E+05 gal), the ARF RF = 6.5E-06, and the LPF = 7.5E-01. The source-term was calculated as follows:

$$(5.0E+05\ L) \cdot (6.5E-06) \cdot (7.5E-01) = 2.4\ L\ (0.6\ gal)$$

E.2.2.2.2 Probability of Hydrogen Deflagration in Waste Storage Tank

The frequency of a hydrogen deflagration in a waste storage tank was estimated at 7.2E-03 per year for the tank farms (LANL 1995). The probability for this scenario based on 100 years of operation was therefore estimated to be 7.2E-01.

E.2.2.2.3 Radiological Consequence from Hydrogen Deflagration in Waste Storage Tank

The radiological dose to the receptors from the previous source-term was calculated by the GENII computer code (Napier et al. 1988) using the methodology previously discussed in Section 1.1.6. The results are presented in Table E.2.2.8.

Table E.2.2.8 Dose Consequence from Hydrogen Deflagration in Waste Storage Tank

E.2.2.2.4 Radiological Cancer Risk from Hydrogen Deflagration in Waste Storage Tank

In the bounding scenario a ll 10 workers would potentially receive a fatal dose and would assumably die directly after the exposure. There would also be 10 LCFs attributed to the exposure to the noninvolved workers and 2 LCFs to the general public if the accident occurred. The LCFs and LCF point estimate risk are presented in Table E.2.2.9. The nominal scenario calculations show there would be no LCFs.

Table E.2.2.9 Latent Cancer Fatality Risk from Hydrogen Deflagration in Waste Storage Tank

E.2.2.2.5 Chemical Consequences from Hydrogen Deflagration in Waste Storage

The chemical exposure to the receptors from the postulated accident was calculated in Appendix A of the accident data package (Shire et al. 1995 and Jacobs) and summarized in the exposure column in Tables E.2.2.10 and E.2.2.11 nominal and bounding toxic effects, respectively and Tables E.2.2.12 and E.2.2.13 for nominal and bounding corrosive/irritant effects, respectively. The tables compare the concentration of the postulated chemical releases to acute exposure criteria (ERPGs) discussed in Section 1.1.7.

Table E.2.2.10 Comparison of Nominal Chemical Concentrations to Toxic Concentration Limits for Hydrogen Deflagration in Waste Storage Tank

Table E.2.2.11 Comparison of Bounding Chemical Concentrations to Toxic Concentration Limits for Hydrogen Deflagration in Waste Storage Tank

Table E.2.2.12 Comparison of Nominal Chemical Concentrations to Corrosive/Irritant Concentration Limits for Hydrogen Deflagration in Waste Storage Tank

Table E.2.2.13 Comparison of Bounding Chemical Concentrations to Corrosive/Irritant Concentration Limits for Hydrogen Deflagration in Waste Storage Tank

Under bounding conditions c hemical impacts were not evaluated for the MEI worker because all workers would receive a lethal radiation dose, as discussed previously.

Toxic Impact from Chemical Exposure

Under nominal conditions (Table E.2.2.10), the cumulative acute hazard ratio for the MEI worker was 1.57 for ERPG-2, indicating that reversible acute health effects would be expected. This acute hazard ratio was primarily attributable to TOC (approximately 87 percent of the overall ERPG-2 ratio). The TOC is assumed to be equivalent in toxicity to tributylphosphate which is the most acutely toxic constituent of the organic analytes identified. Tributylphosphate was used as a surrogate because an inventory of the various chemicals that make up the TOC class is not available. For the MEI noninvolved worker, the cumulative acute hazard ratio for ERPG-3 was 9.38, indicating the potential for irreversible health effects that could be life-threatening. This acute hazard ratio was also primarily attributable to TOC (approximately 90 percent of the overall ERPG-3 ratio) However, the MEI noninvolved worker is a hypothetical worker assumed to be located 100m (330 ft) from the source area. The first, anticipated noninvolved worker population is located 290 m (950 ft) from the source area and had no cumulative acute hazard ratios greater than 1.0 for any of the ERPGs, indicating that no acute health effects would be expected for the nearest noninvolved worker population. Likewise, no acute health effects were predicted for the MEI general public under nominal conditions.

Under bounding conditions (Table E.2.2.11), the cumulative acute hazard ratio for the MEI noninvolved worker was 4.54E+02 for ERPG-3, indicating the potential for irreversible health effects that could be life-threatening. This acute hazard ratio is primarily attributable to:

- Oxalate (approximately 37 percent of the total hazard ratio);
- Beryllium (approximately 13 percent of the total hazard ratio);
- Cadmium (approximately 14 percent of the total hazard ratio);
- Uranium (approximately 12 percent of the total hazard ratio); and
- TOC (approximately 8 percent of the total hazard ratio).

As discussed previously, this is a hypothetical receptor located 100m (330 ft) from the source. The cumulative acute hazard ratio for the nearest noninvolved worker population located 290 m (950 ft) from the source was 1.65 for ERPG-3, indicating the potential for irreversible health effects that could be life-threatening for 335 workers. This hazard ratio was attributable to the same toxic chemicals listed above. This exceedance of the ERPG-3 criterion for the nearest noninvolved worker population would not be expected to result in irreversible health effects or place these workers in a life-threatening situation for the following reasons.

- ERPG-3 is defined as a concentration in which a receptor can be exposed for 1 hour without irreversible health effects. Because the Hanford Site has an in-place emergency response plan designed to evacuate workers within 1 hour of an accident, workers would be expected to evacuate their location and move to an area where potential exposures would be well below ERPG-3. Therefore, this worker population would not be exposed to airborne concentrations that would be either life threatening or result in irreversible health effects.
- The estimated air concentrations of chemicals as a result of this accident were based on very conservative meteorology, which results in movement of a plume directly toward the worker population at a relatively slow rate with minimal wind dispersion. If less conservative meteorological parameters were used, wind dispersion would cause the estimated air concentrations of chemicals to be substantially less, and the ERPG-3 criterion would not be exceeded.
- Only the bounding toxic chemical evaluation exceeded ERPG-3, while the nominal evaluation was well below 1.00 for ERPG-3, suggesting that the noninvolved worker population would not receive an exposure that would result in any permanent health effects.

The next nearest noninvolved worker population is located 1,780 (5,840 ft) from the source and contains 1,500 workers. The cumulative acute hazard ratio was less than 1.0 for all ERPGs, indicating that no acute health effects would be expected for this population of workers. No acute health impacts were predicted for the MEI general public.

Corrosive/Irritant Impact from Chemical Exposure

Under nominal conditions (Table E.2.2.12), the cumulative acute hazard ratio for the MEI worker was 3.82 for ERPG-3, indicating the potential for irreversible corrosive/irritant effects that could be life-threatening. For the MEI noninvolved worker, the cumulative acute hazard ratio for ERPG-3 was 7.89E+01 and would indicate irreversible corrosive/irritant effects that could be life threatening for this hypothetical receptor. This hazard ratio was primarily attributable to sodium which was assumed to be equivalent to sodium hydroxide in corrosive/irritant effects. For the nearest noninvolved worker population (290 m [950 ft]) composed of 335 workers, the cumulative acute hazard ratio for ERPG-1 was 1.38E+01, indicating that only mild reversible effects would be expected. No acute health impacts were predicted for the MEI general public under nominal conditions.

Under bounding conditions (Table E.2.2.13), the cumulative acute hazard ratio for the MEI noninvolved worker was 1.91E+02 for ERPG-3, indicating irreversible health effects that could be life threatening for this hypothetical receptor. This hazard ratio was primarily attributable to:

- Sodium as sodium hydroxide (approximately 75 percent of the total hazard ratio);
- Chromium (approximately 14 percent of the total hazard ratio); and
- Calcium (approximately 6 percent of the total hazard ratio).

For the nearest noninvolved worker population (290 m [950 ft]) composed of 335 workers, the cumulative acute hazard ratio was 1.74 for ERPG-2, indicating that reversible acute effects would be expected. No acute health impacts were predicted for the MEI general public under nominal conditions.

Under both nominal and bounding conditions, the probability of a hydrogen deflagration event in a waste storage tank is 7.20E-01.

E.2.2.3 Beyond Design Basis Accidents

The beyond design basis accident is a seismic event resulting in the collapse of a SST. In the event of a 0.43 g earthquake, a SST could potentially collapse (LANL 1995). This event is not dependent on the remediation alternative but has the same annual frequency regardless of the alternative that is chosen. The length of time unremediated waste would remain in tanks that have not been backfilled would vary depending on the alternative and would affect the probability of the event. The probability of the event is the product of the annual frequency of the earthquake and the number of years the waste remains untreated in the unstabilized tanks.

At smaller annual frequencies, larger earthquakes could occur resulting in greater destruction and larger numbers of

LCF to the onsite and offsite populations. In addition to population exposures from the collapsed SSTs, the impact to other Hanford Site facilities and operations would potentially add to the chemical and radiological risk. This would be a severe earthquake that would cause catastrophic structural damage in the Tri-Cities and the Hanford Site with expected extensive loss of life. There would be injuries and fatalities resulting from collapsed buildings and homes, fires, and traffic accidents. However, this section evaluates the radiological and chemical impacts resulting from the collapse of one SST.

E.2.2.3.1 Source-Term Development

It was conservatively assumed that the radiological and chemical contaminants in the headspace are available for release. The collapse of a portion of the dome and overburden compresses the vapor in the headspace as it descends, enhancing the vapor release rate by a sudden pressure difference. Assuming for each tank a respirable concentration of contaminants in the headspace of 100 mg/m^3, a liquid specific gravity (SpG) of 1.5, and a headspace volume of 1,000 m^3 (Shire et al. 1995 and Jacobs 1996), the potential source-term contribution from the headspace release was calculated as follows:

$$(100 \text{ mg/m}^3) \cdot (1 \text{ g/1,000 mg}) \cdot (1 \text{ L/1,000 g}) \cdot (1{,}000 \text{ m}^3) \cdot (1/1.5) = 6.67\text{E-02 L } (1.8\text{E-02 gal}).$$

It was conservatively assumed that the liquids had been pumped from the tanks so that the tanks contained only solids and the MAR was 2,500 L (660 gal) for each tank. It was postulated that the fall of the dome and overburden generated an air movement sufficient to suspend a fraction the MAR. Assuming the respirable release fraction to be 2.0E-03 (Shire et al. 1995 and Jacobs 1996), the potential source-term contribution was calculated as follows:

$$(2{,}500 \text{ L}) \cdot (2.0\text{E-03}) = 5.0 \text{ L } (1.3 \text{ gal}).$$

It was postulated that prevailing winds resuspend a respirable fraction of the MAR (2,500 L [660 gal]). A respirable release fraction of 4.0E-05/hr for 24 hours was assumed. The potential source-term contribution from resuspension was calculated as follows:

$$(2{,}500 \text{ L}) \cdot (4.0\text{E-05/hr}) \cdot (24 \text{ hr}) = 2.4 \text{ L } (0.6 \text{ gal}).$$

The combined source-term for the acute release is calculated as follows:

$$(6.67\text{E-02 L}) + (5.00\text{E+00 L}) + (2.4 \text{ L}) = 7.4 \text{ L } (2.0 \text{ gal}).$$

E.2.2.3.2 Probability of a Beyond Design Basis Earthquake

This earthquake has a calculated annual exceedance frequency of approximately 1.40E-04 (WHC 1996b). The probability for this scenario based on 100 years of operation was therefore estimated to be 1.40E-02.

E.2.2.3.3 Radiological Consequences from a Beyond Design Basis Earthquake

The radiological dose to the receptors from the previous source-term was calculated by the GENII computer code (Napier et al. 1988) using the methodology previously discussed in Section E.1.1.6. The results are presented in Table E.2.2.14.

Table E.2.2.14 Dose Consequence from Seismic Event

E.2.2.3.4 Radiological Cancer Risk from a Beyond Design Basis Earthquake

The LCFs and LCF point estimate risk are presented in Table E.2.2.15.

Table E.2.2.15 Latent Cancer Fatality Risk from Seismic Event

In the bounding scenario, all 10 workers would potentially receive a fatal dose and assumably die directly after the exposure. There would also be 10 LCFs attributed to the exposure to the noninvolved workers and two LCFs to the general public if the accident occurred. The nominal scenario calculations show there would be no LCFs.

E.2.2.3.5 Chemical Consequences from a Beyond Design Basis Earthquake

The chemical exposure to the receptors from the postulated accident was calculated in Appendix A of the accident data package (Shire et al. 1995 and Jacobs 1996) and summarized in the exposure column in Tables E.2.2.16 and E.2.2.17 for the nominal and bounding toxic effects, respectively, and Tables E.2.2.18 and E.2.2.19 for the nominal and bounding corrosive/irritant effects, respectively. The tables compare the concentration of postulated chemical releases to acute exposure criteria (ERPGs) discussed in Section 1.1.7.

Table E.2.2.16 Comparison of Nominal Chemical Concentrations to Toxic Concentration Limits for Earthquake - 1 Tanks Collapse - SST Solids

Table E.2.2.17 Comparison of Bounding Chemical Concentrations to Toxic Concentration Limits for Earthquake - 1 Tank Collapse - SST Solids

Table E.2.2.18 Comparison of Nominal Chemical Concentrations to Corrosive/Irritant Concentration Limits for Earthquake - 1 Tanks Collapse - SST Solids

Table E.2.2.19 Comparison of Bounding Chemical Concentrations to Corrosive/Irritant Concentration Limits for Earthquake - 1 Tanks Collapse - SST Solids

Under bounding conditions, chemical impacts were not evaluated for the MEI worker because all workers would receive a lethal radiation dose, as discussed previously.

Toxic Impact from Chemical Exposure

Under nominal conditions (Table E.2.2.16), the cumulative acute hazard ratio for the MEI worker was 2.64E+00 for ERPG-1, indicating that only mild transient effects would be expected. For the MEI noninvolved worker, the cumulative acute health hazard was 2.59E+00 for ERPG-3, indicating the potential for irreversible health effects that could be life threatening. This acute hazard ratio was primarily attributable to TOC (approximately 84 percent of the total hazard ratio). The TOC is assumed to be equivalent in toxicity to tributylphosphate which is the most acutely toxic constituent of the organic analytes identified. Tributylphosphate was used as a surrogate because an inventory of the various chemicals that make up the TOC class is not available. The cumulative acute hazard ratio, for the nearest noninvolved worker population consisting of 335 workers located 290 m (950 ft) away, was less than 1.0 for all ERPGs, suggesting that no acute health effects would be expected. No acute health effects are calculated to occur for the MEI general public under nominal conditions.

Under bounding conditions (Table E.2.2.17), the cumulative hazard ratios for the MEI and nearest noninvolved worker (335 workers located 290 m [950 ft] away) were 2.15E+03 and 7.80 for ERPG-3, respectively. These ratios were primarily attributable to:

- Uranium (approximately 47 percent of the total hazard ratio);
- Oxalate (approximately 24 percent of the total hazard ratio); and
- Mercury (approximately 13 percent of the total hazard ratio).

This exceedance of the ERPG-3 criterion for the nearest noninvolved worker population would not be expected to result in irreversible health effects or place these workers in a life-threatening situation for the following reasons.

- ERPG-3 is defined as a concentration in which a receptor can be exposed for 1 hour without irreversible health effects. Because the Hanford Site has an in-place emergency response plan designed to evacuate workers within 1 hour of an accident, workers would be expected to evacuate their location and move to an area where potential

exposures would be well below ERPG-3. Therefore, this worker population would not be exposed to airborne concentrations that would be either life threatening or result in irreversible health effects.
- The estimated air concentrations of chemicals as a result of this accident were based on very conservative meteorology, which results in movement of a plume directly toward the worker population at a relatively slow rate with minimal wind dispersion. If less conservative meteorological parameters were used, wind dispersion would cause the estimated air concentrations of chemicals to be substantially less, and the ERPG-3 criterion would not be exceeded.
- Only the bounding toxic chemical evaluation exceeded ERPG-3, while the nominal evaluation was well below 1.00 for ERPG-3, suggesting that the noninvolved worker population would not receive an exposure that would result in any permanent health effects.

The cumulative acute hazard ratio for the next nearest noninvolved worker population, composed of 1,500 people and located 1,780 (5,840 ft) away, was 2.15 for ERPG-2, indicating that reversible acute health effects would be expected. The cumulative acute hazard ratio for the MEI general public was 1.76E+00 for ERPG-2, indicating that reversible acute health effects would be expected.

Corrosive/Irritant Impact from Chemical Exposure

Under nominal conditions (Table E.2.2.18), the cumulative acute hazard ratios for the MEI worker, MEI noninvolved worker and nearest noninvolved worker (335 workers at 290 m [950 ft]) were 2.47E+01, 5.10E+02 and 1.85E+00, respectively for ERPG-3, indicating the potential for irreversible health effects that could be life threatening. These ratios were almost entirely attributable to sodium which was assumed to be equivalent to sodium hydroxide in corrosive/irritant effects. This exceedance of the ERPG-3 criterion for the nearest noninvolved worker population would not be expected to result in irreversible health effects or place these workers in a life-threatening situation for the following reasons.

- ERPG-3 is defined as a concentration in which a receptor can be exposed for 1 hour without irreversible health effects. Because the Hanford Site has an in-place emergency response plan designed to evacuate workers within 1 hour of an accident, workers would be expected to evacuate their location and move to an area where potential exposures would be well below ERPG-3. Therefore, this worker population would not be exposed to airborne concentrations that would be either life threatening or result in irreversible health effects.
- The estimated air concentrations of chemicals as a result of this accident were based on very conservative meteorology, which results in movement of a plume directly toward the worker population at a relatively slow rate with minimal wind dispersion. If less conservative meteorological parameters were used, wind dispersion would cause the estimated air concentrations of chemicals to be substantially less, and the ERPG-3 criterion would not be exceeded.
- Only the bounding toxic chemical evaluation exceeded ERPG-3, while the nominal evaluation was well below 1.00 for ERPG-3, suggesting that the noninvolved worker population would not receive an exposure that would result in any permanent health effects.

For the next nearest noninvolved worker population (1,500 workers at 1,780 m [5,840 ft]), the cumulative acute hazard ratio was 1.20 for ERPG-1, indicating that only mild irreversible irritant effects would be anticipated. For the MEI general public, the cumulative acute hazard ratio was less than 1.0 for all ERPGs and no acute health effects would be expected.

Under bounding conditions (Table E.2.2.19), the cumulative acute hazard ratios for the MEI noninvolved worker and nearest noninvolved worker (335 workers at 290 m [950 ft]) were 7.31E+02 and 2.65, respectively for ERPG-3, indicating the potential for irreversible health effects that could be life threatening. These acute hazard ratios were primarily attributable to:

- Sodium (approximately 83 percent of the total hazard ratio); and
- Calcium (approximately 10 percent of the total hazard ratio).

Based on the discussion presented above, no irreversible corrosive/irritant effects would be anticipated for the nearest noninvolved worker population.

For the next nearest noninvolved worker and MEI general public, the cumulative acute hazard ratios were 1.74 and 1.42, respectively for ERPG-1, indicating that only mild, transient irritant effects would be expected.

Under both nominal and bounding conditions, the probability of a seismic event is 1.40E-02.

E.2.2.4 Occupational Injuries and Fatalities from Operations

The total person-years required for operations was estimated at 1.04E+05 (Jacobs 1996) for the 100 years of continued operations. The total recordable injuries or illnesses, lost workday cases, and fatalities were calculated as follows:

Total Recordable Cases = (1.04E+05 person-years) · (2.2E+00 incidences /100 person-years) = 2.29E+03

Lost Workday Cases = (1.04E+05 person-years) · (1.1E+00 incidences/100 person-years)= 1.14E+03

Fatalities = (1.04E+05 person-years) · (3.2E-03 fatalities/100 person-years) = 3.33E+00

E.2.3 POST-REMEDIATION ACCIDENT

For the No Action (tank waste) alternative, the waste would remain in the tanks and the tanks would not be stabilized. During the 100-year institutional control period, the tanks would be maintained. After the 100 years there would be no additional maintenance of the aging tanks (the design life of the tanks would be exceeded) and the tanks would deteriorate and lose their structural strength. With the tanks in an unstable condition, a seismic event (a 0.2 gravity earthquake with an annual frequency of 8.0E-04) collapses the tank dome into the tanks resulting in an acute release of contaminants followed by a chronic release at much lower levels until the waste would be covered with earth by natural forces.

Source-Term Development

It was conservatively assumed that all 177 tanks collapse and that the radiological and chemical contaminants in the headspace are available for release. The collapse of a portion of the dome and overburden compresses the vapor in the headspace as it descends, enhancing the vapor release rate by sudden pressure difference. Assuming for each tank a respirable concentration of contaminants in the headspace of 100 mg/m^3, a liquid SpG of 1.5 and a headspace volume of 1,000 m^3, the potential source-term contribution from the headspace release for 177 tanks was calculated as follows:

$$(100 \text{ mg/m}^3)\ (1 \text{ g/L,000 mg}) \cdot (1 \text{ L/1,000 g}) \cdot (1\text{,000 m}^3) \cdot (1/1.5) \cdot (177) = 1.18\text{E+01 L (3.1 gal)}$$

It was conservatively assumed that the liquids had drained from leaks in the tanks so that the surface was dry and crumbly and the MAR was 2,500 L (660 gal) for each tank. It was postulated that the fall of the dome and overburden generated a substantial air movement to suspend a fraction the MAR. Assuming the respirable release fraction to be 2.0E-03 (Shire et al. 1995 and Jacobs 1996), the potential source-term contribution from entrainment for all 177 tanks was calculated as follows:

$$(2\text{,500 L}) \cdot (2.0\text{E-03}) \cdot (177) = 8.85\text{E+02 L (234 gal)}$$

The combined source-term for the acute release is calculated as follows:

$$(1.18\text{E+01 L}) + (8.85\text{E+02 L}) = 8.97\text{E+02 L (237 gal)}$$

Following the initial release, no corrective action would be taken and the waste would continually be released by air currents lifting a fraction of the waste into the air for 1 year. After the first year it was assumed the waste would be covered by natural forces. It was assumed that the dome and overburden covers most of the waste surface reducing the MAR to 10 percent or 250 L (66 gal) , and a respirable release fraction of 4.0E-05/hr was assumed. The source-term for the chronic release for one year from 177 tanks is calculated as follows:

$$(2.50E+02) \cdot (4.0E\text{-}05/hr) \cdot (8.74E+03\ hr/yr) \cdot (177) = 1.55E+04\ L\ (4{,}090\ gal)$$

Consequence for Tank Dome Collapse

The nominal tank inventory was used in calculating the radiological dose to the receptors. It was assumed that the offsite population size and location remained the same and the onsite population of people living on the Hanford Site was 10 percent of the current Hanford population or 1,090. The radiological dose to the receptors was calculated by the GENII computer code (Napier et al. 1988) using the methodology previously discussed in Section E.1.1.6.

The radiological consequences to the onsite population would result in approximately 42 LCFs. E xposure to toxic chemicals that would exceed the ERPG-3 threshold values by a factor of 2.25E+02.

The radiological consequences to the offsite populations would result in approximately 4 LCFs. The population living closest to the Hanford Site would receive an exposure to toxic chemicals that would exceed the ERPG- 1 threshold value by a factor of 1.08E+01 indicating they would suffer from mild, transient health effects.

E.2.4 SUMMARY OF ACCIDENTS

The potential consequences from nonradiological and nonchemical accidents that include occupational and transportation impacts are summarized in Table E.2.4.1 The LCFs associated with representative accidents for each component of the alternative are summarized in Table E.2.4.2 along with the probability of the accident. The chemical hazards associated with representative accidents for each component of the alternative are summarized in Table E.2.4.3. The chemical hazard is expressed as an exceedance of the ERPG threshold values.

Table E.2.4.1 Summary of Potential Nonradiological/Nonchemical Accident Consequences

Table E.2.4.2 Summary of Potential Radiological Accident Consequences

Table E.2.4.3 Chemical Exposures Resulting from Potential Operations and Transportation Accidents

E.3.0 LONG-TERM MANAGEMENT ALTERNATIVE

This section analyzes the risk resulting from potential accidents associated with the Long-Term Management alternative. The Long-Term Management alternative is to continue safe storage activities. This includes:

- Perform routine management and maintenance activities;
- Continue pumping and evaporation of liquid;
- Construct replacement DSTs and associated evaporators;
- Waste transfer system upgrade (W314); and
- Transfers waste via pipeline to the Evaporator Facility or replacement tanks.

E.3.1 CONSTRUCTION ACCIDENTS

The construction activities associated with the Long-Term Management alternative are discussed in Volume Two, Appendix B of the EIS. It should be noted that there are no radiological or chemical consequences associated with construction accidents because the replacement tanks and associated transfer lines and evaporators would be constructed in uncontaminated areas. Occupational injuries, illnesses, and fatalities resulting from potential construction accidents are calculated in the following text.

Construction would require an estimated 3.75E+03 person-years (Jacobs 1996). The total recordable injuries and illnesses, lost workday cases, and fatalities for the 10 years of construction were calculated using the incidence rates from Table E.1.2.1 as follows:

Total Recordable Cases = (3.75E+03 person-years) · (9.75E+00 incidences/100 person-years) = 3.66E+02

Lost Workday Cases = (3.75E+03 person-years) · (2.45E+00 incidences/100 person-years) = 9.19E+01

Fatalities= (3.75E+03 person-years) · (3.2E-03 fatalities/100 person-years) = 1.2E-01

E.3.2 TRANSPORTATION ACCIDENTS

Transportation activities associated with this alternative are 1) transporting construction material from offsite; and 2) employees commuting to work each day.

E.3.2.1 Radiological Cancer Risk

All operations would be conducted within established operating parameters for the tanks and would not involve transporting radioactive materials by container. Therefore, there would be no radiological cancer risks resulting from transportation. Accidents involving the transfer of waste in the transfer lines are discussed in Section E.3.3.

E.3.2.2 Chemical Exposure

Because there would be very limited transportation of toxic materials (e.g., lubricants for routine operations), it is extremely unlikely there would be any accidents resulting in chemical exposures. Therefore, transportation accidents involving chemical exposures were not quantified.

E.3.2.3 Occupational Injuries and Fatalities Truck and Rail Transportation Accident

Injuries and fatalities resulting from direct impact of transportation accidents are analyzed in this subsection. Truck and rail transportation activities to transport material and supplies to the Hanford Site for this alternative are summarized in Table E.3.2.1. The total distance was calculated by multiplying the number of trips by the round-trip distance.

Table E.3.2.1 Summary of Transportation Activities for the Long-Term Management Alternative

The number of injuries and fatalities were calculated by multiplying the total distance traveled in each zone shown in Table E.3.2.2 by the appropriate unit risk factors shown in Table E.3.2.1. The distance traveled in the population zones were calculated using the methodology previously discussed in Section E.1.3. The expected injuries and fatalities resulting from truck and rail transportation accidents associated with the Long-Term Management alternative are summarized in Table E.3.2.3.

Table E.3.2.2 Distance Traveled in Population Zones for the Long-Term Management Alternative

Table E.3.2.3 Injuries and Fatalities Resulting from Truck and Rail Transportation Accidents for the Long-Term Management Alternative

Employee Traffic

In addition to transporting materials and supplies to and from the Hanford Site by truck and rail, Site workers and other personnel required to perform the various activities would drive to the Site in their vehicles. The total person-years to perform the activities was estimated at 1.08E+05 (Jacobs 1996).

To calculate the expected number of injuries and fatalities resulting from vehicle accidents, the injury/fatality rates discussed in Section E.1.3 were used. The expected number of injuries and fatalities resulting from employee vehicle accidents are calculated as follows:

Injuries = (2.91E+09 km) · (7.1E-07 injuries/km) = 2.08E+03

Fatalities = (2.91E+09 km) · (8.98E-09 fatalities/km) = 2.61E+01

Cumulative Transportation Injuries and Fatalities

The cumulative nonradiological and nontoxicological injuries and fatalities incurred as a direct result of traffic accident impacts are the sum of the truck and rail transport and employee vehicle accidents and are summarized in Table E.3.2.4.

Table E.3.2.4 Cumulative Injuries and Fatalities from Traffic Impacts for the Long-Term Management Alternative

Each person was assumed to work 260 days of the year. The round trip distance traveled to work from the Tri-Cities area was estimated at 140 km (87 mi) with an estimated 1.35 passengers per vehicle (DOE 1994a). The total employee vehicle distance was therefore calculated to be 2.91E+09 km (1.81E+09 mi).

E.3.3 OPERATION ACCIDENTS

The potential exists for accidents resulting from continued operation activities. The continued operations are discussed in Volume Two, Appendix B.

E.3.3.1 Continued Operations Accident - Tank Waste Transfers

The dominant continued operations accident during tank waste transfers is the "mispositioned jumper accident" previously discussed in the No Action (Tank Waste) alternative Section E.2.2.1 and summarized as follows:

Source-term - The source-term resulting from a spray release in Section E.2.2.1.1 was calculated to be 52 L (14 gal).

Probability - The frequency of a mispositioned jumper in Section E.2.2.1.2 was 1.1E-02 per year. The probability of occurrence is based on 20 years of waste transfers to accommodate the retanking operations. Therefore, the probability was calculated to be 2.2E-01.

Radiological Consequences - The radiological consequences presented in Table E.2.2.2 are reproduced in Table E.3.3.1.

Table E.3.3.1 Dose Consequence from Mispositioned Jumper

Radiological Cancer Risk - The LCFs calculated in Section E.2.2.1.4 are the same for the Long-Term Management alternative; however, the LCF risk (point estimate) is not the same because of the difference in probabilities. The LCFs and the LCF risks are calculated in Table E.3.3.2.

Table E.3.3.2 Latent Cancer Fatality Risk from Mispositioned Jumper

The bounding scenario calculations show all 10 workers would potentially receive a fatal dose and would assumably die directly after the exposure if the accident occurred. Approximately seven noninvolved workers would receive fatal cancers, and two LCFs would be incurred to the general public. The nominal scenario calculators show there would be no LCFs.

Chemical Consequences

For the Long-Term Management alternative, the potential acute hazards associated with the mispositioned jumper are the same as the acute hazards presented in Tables E. 2.2.4 and E.2.2.7 for the No Action alternative.

Toxic Impact From Chemical Exposure

Under nominal conditions (Table E.2.2.4), the cumulative acute hazard ratios for the MEI worker, MEI noninvolved worker and MEI general public were less than 1.0, indicating that no adverse acute health effects would be expected for these three receptors. Under bounding conditions (Table E.2.2.5), the MEI worker was not evaluated because death would occur from exposure to radionuclides. The cumulative acute hazard ratio for the MEI noninvolved worker was 5.36E+00 for ERPG-2, indicating that reversible acute health effects would be expected. This acute hazard ratio was primarily attributable to mercury (approximately 89 percent of the overall hazard ratio). No adverse acute health effects were predicted for the MEI general public under bounding conditions.

Corrosive/Irritant Impact from Chemical Exposure

Under nominal conditions (Table E.2.2.6), the cumulative acute hazard ratio for the MEI worker was 2.70E+00 for ERPG-3, indicating the potential for irreversible health effects that could be life-threatening. This acute hazard ratio was almost entirely attributable to sodium assumed to be equivalent to sodium hydroxide in corrosive/irritant effects. For the MEI noninvolved worker, the cumulative acute hazard ratio for ERPG-1 was 3.0E+00, indicating that only mild, reversible irritant effects would be expected. No acute health impacts were predicted for the MEI general public under nominal conditions. Under bounding conditions (Table E.2.2.7), the MEI worker was not evaluated because death would occur from exposure to radionuclides. For the MEI noninvolved worker, the cumulative acute hazard ratio for ERPG-1 was 4.36E+00, indicating that only mild reversible irritant effects would be expected. No acute health impacts were predicted for the MEI general public under bounding conditions.

Under both nominal and bounding conditions, the probability of a mispositioned jumper is 2.20E-01.

E.3.3.2 Continued Operations Accident - Waste Storage Tanks

The dominant accident is a hydrogen deflagration in a waste storage tank previously discussed in the No Action alternative in Section E.2.2.2.1 and is summarized as follows:

Source-term - The source-term resulting from a hydrogen deflagration in Section E.2.2.2.1 was calculated to be 2.4 L (0.6 gal).

Probability - The frequency of the hydrogen deflagration in a waste storage tank in Section E.2.2.2.2 was estimated to be 7.2E-03 per year. The probability of the scenario based on 100 years of operation was therefore estimated to be 7.2E-01.

Radiological Consequences - The radiological consequences presented in Table E.2. 2.8 are reproduced in Table E.3.3.3.

Table E.3.3.3 Dose Consequence from Hydrogen Deflagration in Waste Storage Tank

Radiological Cancer Risk

The LCFs calculated in Section E.2.2.2.4 are reproduced in Table E.3.3.4.

Table E.3.3.4 Latent Cancer Fatality Risk from Hydrogen Deflagration in Waste Storage Tank

In the bounding scenario all 10 workers would potentially receive a fatal dose and would assumably die directly after the exposure. T here would also be 10 LCFs attributed to the exposure to the noninvolved workers and 2 LCFs to the general public if the accident occurred. The nominal scenario calculations show there would be no LCFs.

Chemical Consequences

The potential acute hazards associated with the hydrogen deflagration in a waste storage tank are summarized in Table E. 2.2.10 through E.2.2.13 for toxic and corrosive/irritant effects, respectively.

Under bounding conditions c hemical impacts were not evaluated for the worker because all workers would receive a lethal radiation dose as discussed previously.

Toxic Impact from Chemical Exposure

Under nominal conditions (Table E.2.2.10), the cumulative acute hazard ratio for the MEI worker was 1.57 for ERPG-2, indicating that reversible acute health effects would be expected. This acute hazard ratio was primarily attributable to TOC (approximately 87 percent of the overall ERPG-2 ratio). The TOC is assumed to be equivalent in toxicity to tributylphosphate which is the most acutely toxic constituent of the organic analytes identified. Tributylphosphate was used as a surrogate because an inventory of the various chemicals that make up the TOC class is not available. For the MEI noninvolved worker, the cumulative acute hazard ratio for ERPG-3 was 9.38, indicating the potential for irreversible health effects that could be life-threatening. This acute hazard ratio was also primarily attributable to TOC (approximately 90 percent of the overall ERPG-3 ratio) However, the MEI noninvolved worker is a hypothetical worker assumed to be located 100m (330 ft)from the source area. The first, anticipated noninvolved worker population is located 290 m (950 ft) from the source area and had no cumulative acute hazard ratios greater than 1.0 for any of the ERPGs, indicating that no acute health effects would be expected for the nearest noninvolved worker population. Likewise, no acute health effects were predicted for the MEI general public under nominal conditions.

Under bounding conditions (Table E.2.2.11), the cumulative acute hazard ratio for the MEI noninvolved worker was 4.54E+02 for ERPG-3, indicating the potential for irreversible health effects that could be life-threatening. This acute hazard ratio is primarily attributable to:

- Oxalate (approximately 37 percent of the total hazard ratio);
- Beryllium (approximately 13 percent of the total hazard ratio);
- Cadmium (approximately 14 percent of the total hazard ratio);
- Uranium (approximately 12 percent of the total hazard ratio); and
- TOC (approximately 8 percent of the total hazard ratio).

As discussed previously, this is a hypothetical receptor located 100m (330 ft)from the source. The cumulative acute hazard ratio for the nearest noninvolved worker population located 290 m (950 ft) from the source was 1.65 for ERPG-3, indicating the potential for irreversible health effects that could be life-threatening for 335 workers. This hazard ratio was attributable to the same toxic chemicals listed above. This exceedance of the ERPG-3 criterion for the nearest noninvolved worker population would not be expected to result in irreversible health effects or place these workers in a life-threatening situation for the following reasons.

- ERPG-3 is defined as a concentration in which a receptor can be exposed for 1 hour without irreversible health effects. Because the Hanford Site has an in-place emergency response plan designed to evacuate workers within 1 hour of an accident, workers would be expected to evacuate their location and move to an area where potential exposures would be well below ERPG-3. Therefore, this worker population would not be exposed to airborne concentrations that would be either life threatening or result in irreversible health effects.
- The estimated air concentrations of chemicals as a result of this accident were based on very conservative meteorology, which results in movement of a plume directly toward the worker population at a relatively slow rate with minimal wind dispersion. If less conservative meteorological parameters were used, wind dispersion would cause the estimated air concentrations of chemicals to be substantially less, and the ERPG-3 criterion would not be exceeded.
- Only the bounding toxic chemical evaluation exceeded ERPG-3, while the nominal evaluation was well below 1.00 for ERPG-3, suggesting that the noninvolved worker population would not receive an exposure that would result in any permanent health effects.

The next nearest noninvolved worker population is located 1,780 (5,840 ft) from the source and contains 1,500 workers. The cumulative acute hazard ratio was less than 1.0 for all ERPGs, indicating that no acute health effects would be expected for this population of workers. No acute health impacts were predicted for the MEI general public.

Corrosive/Irritant Impact from Chemical Exposure

Under nominal conditions (Table E.2.2.12), the cumulative acute hazard ratio for the MEI worker was 3.82 for ERPG-3, indicating the potential for irreversible corrosive/irritant effects that could be life-threatening. For the MEI noninvolved worker, the cumulative acute hazard ratio for ERPG-3 was 7.89E+01 and would indicate irreversible corrosive/irritant effects that could be life threatening for this hypothetical receptor. This hazard ratio was primarily attributable to sodium which was assumed to be equivalent to sodium hydroxide in corrosive/irritant effects. For the nearest noninvolved worker population (290 m [950 ft]) composed of 335 workers, the cumulative acute hazard ratio for ERPG-1 was 1.38E+01, indicating that only mild reversible effects would be expected. No acute health impacts were predicted for the MEI general public under nominal conditions.

Under bounding conditions (Table E.2.2.13), the cumulative acute hazard ratio for the MEI noninvolved worker was 1.91E+02 for ERPG-3, indicating irreversible health effects that could be life threatening for this hypothetical receptor. This hazard ratio was primarily attributable to :

- Sodium as sodium hydroxide (approximately 75 percent of the total hazard ratio);
- Chromium (approximately 14 percent of the total hazard ratio); and
- Calcium (approximately 6 percent of the total hazard ratio).

For the nearest noninvolved worker population (290 m [950 ft]) composed of 335 workers, the cumulative acute hazard ratio was 1.74 for ERPG-2, indicating that reversible acute effects would be expected. No acute health impacts were predicted for the MEI general public under nominal conditions.

Under both nominal and bounding conditions the probability of a hydrogen deflagration event in a waste storage tank is 7.20E-01.

E.3.3.3 Beyond Design Basis Accidents

The beyond design basis accident is a seismic event resulting in the collapse of a SST. In the event of a 0.43 g earthquake, a SST could potentially collapse (LANL 1995). This event is not dependent on the remediation alternative but has the same annual frequency regardless of the alternative that is chosen. The length of time unremediated waste would remain in tanks that have not been backfilled would vary depending on the alternative and would affect the probability of the event. The probability of the event is the product of the annual frequency of the earthquake and the number of years the waste remains untreated in the unstabilized tanks.

At smaller annual frequencies, larger earthquakes could occur resulting in greater destruction and larger numbers of LCF to the onsite and offsite populations. In addition to population exposures from the collapsed SSTs, the impact to other Hanford Site facilities and operations would potentially add to the chemical and radiological risk. This would be a severe earthquake that would cause catastrophic structural damage in the Tri-Cities and the Hanford Site with expected extensive loss of life. There would be injuries and fatalities resulting from collapsed buildings and homes, fires, and traffic accidents. However, this section evaluates the radiological and chemical impacts resulting from the collapse of one SST.

E.3.3.3.1 Source-Term Development

It was conservatively assumed that the radiological and chemical contaminants in the headspace are available for release. The collapse of a portion of the dome and overburden compresses the vapor in the headspace as it descends, enhancing the vapor release rate by a sudden pressure difference. Assuming for each tank a respirable concentration of contaminants in the headspace of 100 mg/m^3, a liquid SpG of 1.5, and a headspace volume of 1,000 m^3 (Shire et al. 1995 and Jacobs 1996), the potential source-term contribution from the headspace release was calculated as follows:

$$(100\ \text{mg/m}^3) \cdot (1\ \text{g/1,000 mg}) \cdot (1\ \text{L/1,000 g}) \cdot (1{,}000\ \text{m}^3) \cdot (1/1.5) = 6.67\text{E-02 L } (1.8\text{E-02 gal}).$$

It was conservatively assumed that the liquids had been pumped from the tanks so that the tanks contained only solids and the MAR was 2,500 L (660 gal) for each tank. It was postulated that the fall of the dome and overburden generated a air movement sufficient to suspend a fraction the MAR. Assuming the respirable release fraction to be 2.0E-03 (Shire et al. 1995 and Jacobs 1996), the potential source-term contribution was calculated as follows:

$$(2{,}500\ \text{L}) \cdot (2.0\text{E-03}) = 5.0\ \text{L } (1.3\ \text{gal}).$$

It was postulated that prevailing winds resuspend a respirable fraction of the MAR (2,500 L [660 gal]). A respirable release fraction of 4.0E-05/hr for 24 hours was assumed. The potential source-term contribution from resuspension was calculated as follows:

$$(2{,}500\ \text{L}) \cdot (4.0\text{E-05/hr}) \cdot (24\ \text{hr}) = 2.4\ \text{L } (0.6\ \text{gal}).$$

The combined source-term for the acute release is calculated as follows:

$$(6.67\text{E-02 L}) + (5.00\text{E+00 L}) + (2.4\ \text{L}) = 7.4\ \text{L } (2.0\ \text{gal}).$$

E.3.3.3.2 Probability of a Beyond Design Basis Earthquake

This earthquake has a calculated annual exceedance frequency of approximately 1.40E-04 (WHC 1996b). The probability for this scenario based on 100 years of operation was therefore estimated to be 1.40E-02.

E.3.3.3.3 Radiological Consequences from a Beyond Design Basis Earthquake

The radiological dose to the receptors from the previous source-term was calculated by the GENII computer code (Napier et al. 1988) using the methodology previously discussed in Section E.1.1.6. The results are presented in Table E.3.3.5.

Table E.3.3.5 Dose Consequence from Seismic Event

E.3.3.3.4 Radiological Cancer Risk from a Beyond Design Basis Earthquake

The LCFs and LCF point estimate risk are presented in Table E.3.3.6

Table E.3.3.6 Latent Cancer Fatality Risk from Seismic Event

In the bounding scenario, all 10 workers would potentially receive a fatal dose and assumably die directly after the exposure. There would also be 10 LCFs attributed to the exposure to the noninvolved workers and two LCFs to the general public if the accident occurred. The nominal scenario calculations show there would be no LCFs.

E.3.3.3.5 Chemical Consequences from a Beyond Design Basis Earthquake

For the Long-Term Management alternative, the potential acute hazards associated with a beyond design basis earthquake are the same as the acute hazards presented in Tables E.2.2.16 (toxic chemicals, nominal conditions), E.2.2.17 (toxic chemicals, bounding conditions), E.2.2.18 (corrosive/irritant chemicals, nominal conditions) and E.2.2.19 (corrosive/irritant chemicals, bounding conditions) for the No Action alternative.

Under bounding conditions, chemical impacts were not evaluated for the MEI worker because all workers would receive a lethal radiation dose, as discussed previously.

Toxic Impact from Chemical Exposure

Under nominal conditions (Table E.2.2.16), the cumulative acute hazard ratio for the MEI worker was 2.64E+00 for ERPG-1, indicating that only mild transient effects would be expected. For the MEI noninvolved worker, the cumulative acute health hazard was 2.59E+00 for ERPG-3, indicating the potential for irreversible health effects that could be life threatening. This acute hazard ratio was primarily attributable to TOC (approximately 84 percent of the total hazard ratio). The TOC is assumed to be equivalent in toxicity to tributylphosphate which is the most acutely toxic constituent of the organic analytes identified. Tributylphosphate was used as a surrogate because an inventory of the various chemicals that make up the TOC class is not available. The cumulative acute hazard ratio for the nearest noninvolved worker population consisting of 335 workers located 290 m (950 ft) away was less than 1.0 for all ERPGs, suggesting that no acute health effects would be expected.

Under bounding conditions (Table E.2.2.17), the cumulative hazard ratios for the MEI and nearest noninvolved worker (335 workers located 290 m [950 ft] away) were 2.15E+03 and 7.80E+00 for ERPG-3, respectively. These ratios were primarily attributable to:

- Uranium (approximately 47 percent of the total hazard ratio);
- Oxalate (approximately 24 percent of the total hazard ratio); and
- Mercury (approximately 13 percent of the total hazard ratio).

This exceedance of the ERPG-3 criterion for the nearest noninvolved worker population would not be expected to result in irreversible health effects or place these workers in a life-threatening situation for the following reasons.

- ERPG-3 is defined as a concentration in which a receptor can be exposed for 1 hour without irreversible health effects. Because the Hanford Site has an in-place emergency response plan designed to evacuate workers within 1 hour of an accident, workers would be expected to evacuate their location and move to an area where potential exposures would be well below ERPG-3. Therefore, this worker population would not be exposed to airborne concentrations that would be either life threatening or result in irreversible health effects.
- The estimated air concentrations of chemicals as a result of this accident were based on very conservative meteorology, which results in movement of a plume directly toward the worker population at a relatively slow rate with minimal wind dispersion. If less conservative meteorological parameters were used, wind dispersion would cause the estimated air concentrations of chemicals to be substantially less, and the ERPG-3 criterion would not be exceeded.
- Only the bounding toxic chemical evaluation exceeded ERPG-3, while the nominal evaluation was well below

1.00 for ERPG-3, suggesting that the noninvolved worker population would not receive an exposure that would result in any permanent health effects.

The cumulative acute hazard ratio for the next nearest noninvolved worker population, composed of 1,500 people and located 1,780 (5,840 ft) away, was 2.15E+00 for ERPG-2, indicating that reversible acute health effects would be expected. The cumulative acute hazard ratio for the MEI general public was 1.76E+00 for ERPG-2, indicating that reversible acute health effects would be expected.

Corrosive/Irritant Impact from Chemical Exposure

Under nominal conditions (Table E.2.2.18), the cumulative acute hazard ratios for the MEI worker, MEI noninvolved worker and nearest noninvolved worker (335 workers at 290 m [950 ft]) were 2.47E+01, 5.10E+02 and 1.85E+00, respectively for ERPG-3, indicating the potential for irreversible health effects that could be life threatening. These ratios were almost entirely attributable to sodium which was assumed to be equivalent to sodium hydroxide in corrosive/irritant effects. This exceedance of the ERPG-3 criterion for the nearest noninvolved worker population would not be expected to result in irreversible health effects or place these workers in a life-threatening situation for the following reasons.

- ERPG-3 is defined as a concentration in which a receptor can be exposed for 1 hour without irreversible health effects. Because the Hanford Site has an in-place emergency response plan designed to evacuate workers within 1 hour of an accident, workers would be expected to evacuate their location and move to an area where potential exposures would be well below ERPG-3. Therefore, this worker population would not be exposed to airborne concentrations that would be either life threatening or result in irreversible health effects.
- The estimated air concentrations of chemicals as a result of this accident were based on very conservative meteorology, which results in movement of a plume directly toward the worker population at a relatively slow rate with minimal wind dispersion. If less conservative meteorological parameters were used, wind dispersion would cause the estimated air concentrations of chemicals to be substantially less, and the ERPG-3 criterion would not be exceeded.
- Only the bounding toxic chemical evaluation exceeded ERPG-3, while the nominal evaluation was well below 1.00 for ERPG-3, suggesting that the noninvolved worker population would not receive an exposure that would result in any permanent health effects.

For the next nearest noninvolved worker population (1,500 workers at 1,780 m [5,840 ft]), the cumulative acute hazard ratio was 1.20E+00 for ERPG-1, indicating that only mild, irreversible irritant effects would be anticipated. For the MEI general public, the cumulative acute hazard ratio was less than 1.0 for all ERPGs and no acute health effects would be expected.

Under bounding conditions, the cumulative acute hazard ratios for the MEI noninvolved worker and nearest noninvolved worker (335 workers at 290 m [950 ft]) were 7.31E+02 and 2.65E+00, respectively for ERPG-3, indicating the potential for irreversible health effects that could be life threatening. These acute hazard ratios were primarily attributable to:

- Sodium (approximately 83 percent of the total hazard ratio); and
- Calcium (approximately 10 percent of the total hazard ratio).

Based in the discussion presented above, even through the acute hazard ratio exceeded ERPG-3, the noninvolved worker population would not experience irreversible health effects.

For the next nearest noninvolved worker and MEI general public, the cumulative acute hazard ratios were 1.74E+00 and 1.42E+00, respectively for ERPG-1, indicating that only mild, transient irritant effects would be expected.

Under both nominal and bounding conditions, the probability of a seismic event is 1.40E-02.

E.3.3. 4 Occupational Injuries and Fatalities from Operations

The number of operation personnel was estimated at 1.04E+05 person-years (Jacobs 1996) during 100 years of routine operations. The total recordable injuries or illnesses, lost workday cases, and fatalities were calculated as follows:

Total Recordable Cases = (1.04E+05 person-years) · (2.2E+00 incidences/100 person-years) = 2.29E+03

Lost Workday Cases = (1.04E+05 person-years) · (1.1E+00 incidences/100 person-years) = 1.14E+03

Fatalities = (1.04E+05 person-years) · (3.2E-03 fatalities/100 person-years) = 3.33E+00

E.3.4 POST-REMEDIATION ACCIDENT

The post remediation accident for the Long-Term Management alternative would be the tanks collapsing due to an earthquake, as discussed in Section E.2.3. The radiological consequences to the onsite population would result in approximately 42 LCFs. E xposure to toxic chemicals would exceed the ERPG-3 threshold values by a factor of 2.25E+02.

The radiological consequences to the offsite population would result in approximately 4 LCFs. The population living closest to the Hanford Site would receive an exposure to toxic chemicals that would exceed the ERPG-2 threshold value by a factor of 1.08E+01 indicating they would suffer from mild, transient health effects.

E.3.5 SUMMARY OF ACCIDENTS

The potential consequences from nonradiological and nonchemical accidents that include occupational and transportation impacts are summarized in Table E.3.5.1. The LCFs associated with representative accidents for each component of the alternative are summarized in Table E.3.5.2 along with the probability of the accident. The chemical hazards associated with representative accidents for each component of the alternative are summarized in Table E.3.5.3. The chemical hazard is expressed as an exceedance of the ERPG threshold values.

Table E.3.5.1 Summary of Potential Nonradiological/Nonchemical Accident Consequences

Table E.3.5.2 Summary of Potential Radiological Accident Consequences

Table E.3.5.3 Chemical Exposures Resulting from Potential Operations and Transportation Accidents

E.4.0 IN SITU FILL AND CAP ALTERNATIVE

Under this alternative, all excess liquid from the DSTs would be evaporated at the 242-A Evaporator. The tanks would then be backfilled with gravel and a Hanford Barrier would be constructed over the tanks. The waste in the MUSTs would be grouted in situ.

E.4.1 CONSTRUCTION ACCIDENTS

Although construction activities are limited for the In Situ Fill and Cap alternative, the potential exists for accidents. The construction activities are discussed in Appendix B of the EIS.

The number of construction personnel was estimated at 7.25E+02 person-years (Jacobs 1996). The number of total recordable injuries and illnesses, lost workday cases, and fatalities were calculated using the incidence rates from Table E.1.2.1 as follows.

Total Recordable Cases = (7.25E+02 person-years) · (9.75E+00 incidences/100 person-years) = 7.07E+01

Lost Workday Cases = (7.25E+02 person-years) · (2.45E+00 incidences/100 person-years) = 1.78E+01

Fatalities = (7.25E+02 person-years) · (3.20E-03 fatalities/100 person-years) = 2.32E-02

E.4.2 TRANSPORTATION ACCIDENTS

Transporting activities associated with this alternative include:

- Transporting construction material from offsite for the waste transfer system upgrade (W-314);
- Transporting cement from offsite to grout MUSTs;
- Transporting sand and gravel from the Pit 30 borrow site to grout MUSTs;
- Transporting earthen material from onsite borrow sites for the Hanford Barrier; and
- Employees commuting to work each day.

E.4.2.1 Radiological Cancer Risk

All operations would be conducted within established operating parameters for the tanks and would not involve transporting radioactive materials by container. Therefore, there would be no radiological cancer risks from transportation.

E.4.2.2 Chemical Exposure

Because there would be very limited transportation of toxic materials (e.g., lubricants for routine operations), it is extremely unlikely there would be any accidents resulting in chemical exposures. Therefore, transportation accidents involving chemical exposures were not quantified.

E.4.2.3 Occupational Injuries and Fatalities

Truck Transport Accidents

Injuries and fatalities resulting from direct impact of transportation accidents are analyzed in this subsection. Truck transportation activities to transport materials and supplies to the Hanford Site for this alternative were estimated

(Jacobs 1996) and are summarized in Table E.4.2.1.

Table E.4.2.1 Summary of Transportation Activities for the In Situ Fill and Cap Alternative

The number of injuries and fatalities were calculated by multiplying the total distance traveled in each zone shown in Table E.4.2.2 by the appropriate unit risk factors shown in Table E.1.3.1. The distance traveled in the population zones were calculated using the methodology previously discussed in Section E.1.3.

Table E.4.2.2 Distance Traveled in Population Zones for the In Situ Fill and Cap Alternative

The expected injuries and fatalities resulting from transportation accidents associated with the In Situ Fill and Cap alternative are summarized in Table E.4.2.3.

Table E.4.2.3 Injuries and Fatalities Resulting from Truck Transportation Accidents for the In Situ Fill and Cap Alternative

Employee Traffic

In addition to transporting materials and supplies to and from the Hanford Site by truck, site workers and other personnel required to perform the various activities would be driving to the site in their vehicles. The total person-years to perform the activities was estimated at 2.61E+04 (Jacobs 1996). Each person was assumed to work 260 days of the year. The round-trip distance traveled to work from the Tri-Cities area was estimated at 140 km (87 mi) with an estimated 1.35 passengers per vehicle (DOE 1994a). The total employee vehicle distance was therefore calculated as follows:

$$(2.61E+04 \text{ person-years}) \cdot (260 \text{ days/year}) \cdot (140 \text{ km/day}) \cdot (1/1.35) = 7.05E+08 \text{ km } (4.37E+08 \text{ mi})$$

To calculate the expected number of injuries and fatalities resulting from vehicle accidents, the injury/fatality rates discussed in Section E.1.3 were used. The expected number of injuries and fatalities resulting from employee vehicle accidents were calculated as follows:

Injuries = (7.05E+08 km) · (7.14E-07 injuries/km) = 5.03E+02

Fatalities = (7.05E+08 km) · (8.98E-09 fatalities/km) = 6.33E+00

Cumulative Transportation Injuries and Fatalities

The cumulative nonradiological and nontoxicological injuries and fatalities incurred as a direct result of traffic accident impacts are the sum of the truck transport and employee vehicle accidents. The results are summarized in Table E.4.2.4.

Table E.4.2.4 Cumulative Injuries and Fatalities from Traffic Impacts for the In Situ Fill and Cap Alternative

E.4.3 OPERATION ACCIDENTS

The potential exists for accidents resulting from operation activities. The operations are discussed in Appendix B.

This analysis separates and analyzes operations according to the following modes of operation:

- Continued operations - These operations have been previously discussed in No Action alternative; and
- Treatment - After excess liquid has been removed from the tank waste the tanks are filled with gravel.

The dominant accident scenarios analyzed in the following subsections were selected from the Accident Screening Table (Table E.4.3.1). The accidents listed in Table E.4.3.1 were taken from the Accident Analysis Data Package (Shire et al. 1995 and Jacobs 1996). The methodology of screening was previously discussed in Section 1.1.2.

Table E.4.3.1 Accident Screening Table for the In Situ Fill and Cap Alternative

E.4.3.1 Continued Operation Accident - Tank Waste Transfers

The dominant continued operations accident during tank waste transfers is the mispositioned jumper accident previously discussed in the No Action alternative (Section E.2.2.1) and summarized as follows**:**

Source-term - The source-term resulting from a spray release in Section E.2.2.1.1 was calculated to be 52 L (14 gal).

Probability - The frequency of a mispositioned jumper in Section E.2.2.1.2 was 1.1E-02 per year. The In Situ Fill and Cap alternative was based on 1 2 years of operations. Therefore, the probability was calculated to be 1.3E-01.

Radiological Consequences - The radiological consequences presented in Table E.2.2.2 were reproduced in Table E.4.3.2.

Table E.4.3.2 Dose Consequence from Mispositioned Jumper

Radiological Cancer Risk - The LCFs calculated in Section E.2.2.1.4 are the same for the In Situ Fill and Cap alternative however, the LCF risk (point estimate) is not the same due to the difference in probabilities. The LCFs and the LCF risk are calculated in Table E.4.3.3. The bounding scenario calculations show all 10 workers would potentially receive fatal dose and would assumably die directly after the exposure if the accident occurred. Approximately seven noninvolved workers would receive fatal cancers, and two LCFs would be incurred to the general public. The nominal scenario calculations show there would be no LCFs.

Table E.4.3.3 Latent Cancer Fatality Risk from Mispositioned Jumper

Chemical Consequences

Potential acute hazards associated with a mispositioned jumper accident are summarized in Tables E.2.2.4 (toxic chemicals, nominal conditions), E.2.2.5 (toxic chemicals, bounding conditions), E.2.2.6 (corrosive/irritant chemicals, nominal conditions) and E.2.2.7 (corrosive/irritant bounding conditions) for the No Action alternatives.

Toxic Impact from Chemical Exposure

Under nominal conditions (Table E.2.2.4), the cumulative acute hazard ratios for the MEI worker, MEI noninvolved worker, and MEI general public were less than 1.0E+00, indicating that no adverse acute health effects would be expected for these three receptors. Under bounding conditions (Table E.2.2.5), the MEI worker was not evaluated because death would occur from exposure to radionuclides. The cumulative acute hazard ratio for the MEI noninvolved worker was 5.36E+00 for ERPG-2, indicating that reversible acute health effects would be expected. This acute hazard ratio was primarily attributable to mercury (approximately 89 percent of the overall hazard ratio). No adverse acute health effects were predicted for the MEI general public under bounding conditions.

Corrosive/Irritant Impact from Chemical Exposure

Under nominal conditions (Table E.2.2.6), the cumulative acute hazard ratio for the MEI worker was 2.70E+00 for ERPG-3, indicating the potential for irreversible health effects that could be life threatening. This acute hazard ratio was almost entirely attributable to sodium assumed to be equivalent to sodium hydroxide in corrosive/irritant effects. For the MEI noninvolved worker, the cumulative acute hazard ratio for ERPG-1 was 3.0E+00, indicating that only mild, reversible irritant effects would be expected. No acute health impacts were predicted for the MEI general public under nominal conditions. Under bounding conditions (Table E.2.2.7), the MEI worker was not evaluated because death would occur from exposure to radionuclides. For the MEI noninvolved worker, the cumulative acute hazard ratio for ERPG-1 was 4.36E+00, indicating that only mild, reversible irritant effects would be expected. No acute health impacts were predicted for the MEI general public under bounding conditions.

Under both nominal and bounding conditions, the probability of a mispositioned jumper is 1.32E-01.

E.4.3.2 Continued Operations Accident - Waste Storage Tanks

The dominant accident is a hydrogen deflagration in a waste storage tank previously discussed in the No Action alternative in Section E.2.2.2.1 and summarized as follows:

Source-term - The source-term resulting from a hydrogen deflagration in Section E.2.2.2.1 was calculated to be 2.4 L (0.6 gal).

Probability - The frequency of the hydrogen deflagration in a waste storage tank in Section E.2.2.2.2 was estimated to be 7.2E-03 per year. The probability of the scenario based on 12 years of operation was therefore estimated to be 8.6E-02.

Radiological Consequences - The radiological consequences presented in Table E.2.2.8 are reproduced in Table E.4.3.4.

Table E.4.3.4 Dose Consequence from Hydrogen Deflagration in Waste Storage Tank

Radiological Cancer Risk - The LCFs calculated in Section E.2.2.2.4 are reproduced in Table E.4.3.5.

Table E.4.3.5 Latent Cancer Fatality Risk from Hydrogen Deflagration in Waste Storage Tank

Chemical Consequences

Potential acute hazards associated with a hydrogen deflagration in a waste storage tank are summarized in Tables E.2.2.10 (toxic chemicals, nominal conditions), E.2.2.11 (toxic chemicals, bounding conditions), E.2.2.12 (corrosive/irritant chemicals, nominal conditions) and E.2.2.13 (corrosive/irritant chemicals bounding conditions) for the No Action alternative. Chemical impacts were not evaluated for the MEI worker since all workers would receive a lethal radiation dose, as discussed previously.

In the bounding scenario all 10 workers, would potentially receive a fatal dose and would assumably die directly after the exposure. There would also be 10 LCFs attributed to the exposure to the noninvolved workers and two LCFs to the general public if the accident occurred. The nominal scenario calculations show there would be no LCFs.

Toxic Impact from Chemical Exposure

Under nominal conditions (Table E.2.2.10), the cumulative acute hazard ratio for the MEI worker was 1.57E+00 for ERPG-2, indicating that reversible, acute health effects would be expected. This acute hazard ratio was primarily attributable to TOC (approximately 87 percent of the overall ERPG-2 ratio). The TOC is assumed to be equivalent in toxicity to tributylphosphate, which is the most acutely toxic constituent of the organic analytes identified. Tributylphosphate was used as a surrogate because an inventory of the various chemicals that make up the TOC class is not available. For the MEI noninvolved worker, the cumulative acute hazard ratio for ERPG-3 was 9.38E+00, indicating the potential for irreversible health effects that could be life-threatening. This acute hazard ratio was also primarily attributable to TOC (approximately 90 percent of the overall ERPG-3 ratio) However, the MEI noninvolved worker is a hypothetical worker assumed to be located 100m (330 ft) from the source area. The first anticipated noninvolved worker population is located 290 m (950 ft) from the source area and had no cumulative acute hazard ratios greater than 1.0 for any of the ERPGs, indicating that no acute health effects would be expected for the nearest noninvolved worker population. Likewise, no acute health effects were predicted for the MEI general public under nominal conditions.

Under bounding conditions (Table E.2.2.11), the cumulative acute hazard ratio for the MEI noninvolved worker was 4.54E+02 for ERPG-3, indicating the potential for irreversible health effects that could be life threatening. This acute hazard ratio is primarily attributable to:

- Oxalate (approximately 37 percent of the total hazard ratio);

- Beryllium (approximately 13 percent of the total hazard ratio);
- Cadmium (approximately 14 percent of the total hazard ratio);
- Uranium (approximately 12 percent of the total hazard ratio); and
- TOC (approximately 8 percent of the total hazard ratio).

As discussed previously, this is a hypothetical receptor located 100m (330 ft) from the source. The cumulative acute hazard ratio for the nearest noninvolved worker population located 290 m (950 ft) from the source was 1.65E+00 for ERPG-3, indicating the potential for irreversible health effects that could be life threatening for 335 workers. This hazard ratio was attributable to the same toxic chemicals listed above. This exceedance of the ERPG-3 criterion for the nearest noninvolved worker population would not be expected to result in irreversible health effects or place these workers in a life-threatening situation for the following reasons.

- ERPG-3 is defined as a concentration in which a receptor can be exposed for 1 hour without irreversible health effects. Because the Hanford Site has an in-place emergency response plan designed to evacuate workers within 1 hour of an accident, workers would be expected to evacuate their location and move to an area where potential exposures would be well below ERPG-3. Therefore, this worker population would not be exposed to airborne concentrations that would be either life threatening or result in irreversible health effects.
- The estimated air concentrations of chemicals as a result of this accident were based on very conservative meteorology, which results in movement of a plume directly toward the worker population at a relatively slow rate with minimal wind dispersion. If less conservative meteorological parameters were used, wind dispersion would cause the estimated air concentrations of chemicals to be substantially less, and the ERPG-3 criterion would not be exceeded.
- Only the bounding toxic chemical evaluation exceeded ERPG-3, while the nominal evaluation was well below 1.00E+00 for ERPG-3, suggesting that the noninvolved worker population would not receive an exposure that would result in any permanent health effects.

The next nearest noninvolved worker population is located 1,780 (5,840 ft) from the source and contains 1,500 workers. The cumulative acute hazard ratio was less than 1.0 for all ERPGs, indicating that no acute health effects would be expected for this population of workers. No acute health impacts were predicted for the MEI general public.

Corrosive/Irritant Impact from Chemical Exposure

Under nominal conditions (Table E.2.2.12), the cumulative acute hazard ratio for the MEI worker was 3.82E+00 for ERPG-3, indicating the potential for irreversible corrosive/irritant effects that could be life-threatening. For the MEI noninvolved worker, the cumulative acute hazard ratio for ERPG-3 was 7.89E+01 and would indicate irreversible corrosive/irritant effects that could be life threatening for this hypothetical receptor. This hazard ratio was primarily attributable to sodium, which was assumed to be equivalent to sodium hydroxide in corrosive/irritant effects. For the nearest noninvolved worker population (290 m [950 ft]) composed of 335 workers, the cumulative acute hazard ratio for ERPG-1 was 1.38E+01, indicating that only mild reversible effects would be expected. No acute health impacts were predicted for the MEI general public under nominal conditions.

Under bounding conditions (Table E.2.2.13), the cumulative acute hazard ratio for the MEI noninvolved worker was 1.91E+02 for ERPG-3, indicating irreversible health effects that could be life threatening for this hypothetical receptor. This hazard ratio was primarily attributable to :

- Sodium as sodium hydroxide (approximately 75 percent of the total hazard ratio);
- Chromium (approximately 14 percent of the total hazard ratio); and
- Calcium (approximately 6 percent of the total hazard ratio).

For the nearest noninvolved worker population (290 m [950 ft]) composed of 335 workers, the cumulative acute hazard ratio was 1.74E+00 for ERPG-2, indicating that reversible acute effects would be expected. No acute health impacts were predicted for the MEI general public under nominal conditions.

Under both nominal and bounding conditions, the probability of a hydrogen deflagration event in a waste storage tank is 8.64E-02.

E.4.3. 3 Treatment Accident

The treatment accidents identified in the accident engineering data package (Shire et al. 1995 and Jacobs 1996) are summarized in Table E.4.3.1. The rock slinger ignites gas plume in tank accident, which would lead to a partial tank dome collapse, was identified as the dominant accident.

E.4.3. 3 .1 Scenario and Source-Term Development for Deflagration In Tank During Fill and Cap

It was postulated that hydrogen deflagration could occur while filling the tank with gravel using a rock slinger. A spark from the gravel ignites a hydrogen gas plume, which is suddenly released from the solids or salt cake causing the tank to overpressurize. This in turn causes the HEPA filters to blow out (in the case of DST) or the dome to collapse (in the case of SST). The impact of the postulated accident would result in an airborne release of radionuclides and chemical constituents in the tank.

For this event to occur, the following conditions must exist.

- Flammable gases must be generated from the waste;
- The concentration of the flammable gas must exceed the lower flammability limit;
- There must be an ignition source; and
- The deflagration would have to generate enough energy to blow out the HEPA filters or collapse the tank dome.

Generation of Flammable Gas

All 177 waste tanks produce flammable gases at the molecular level such as hydrogen, ammonia, and methane due to radiolysis and organic degradation. The generation of flammable gas has been demonstrated in all the tanks and has resulted in 25 tanks being included on the Watchlist for hydrogen buildup. These 25 tanks include 19 SSTs and 6 DSTs.

Gas Concentration

Gases that are constantly being released into the headspace, and subsequently removed from the tank through the tank ventilation system, are unable to reach the lower flammability limits and do not pose a potential hydrogen deflagration event. Active ventilation systems can be engineered to provide removal of flammable gases and prevent gas concentrations from reaching 25 percent of the LFL.

Of concern are conditions in which the gas is not readily released from the waste leading to retention of substantial volumes of gas in the waste matrix. These trapped pockets of gas could be triggered into an instant release by pressure from the fill material on the tank waste. This would result in a gas plume in the head space. Studies made on the flammable gas Watchlist tanks (LANL 1995) have shown the potential for concentrations of hydrogen in these gas pockets to exceed the LFL. The composition of the mixture is important. If the mixture is hydrogen and air, it takes a relatively small ignition source (0.01 mJ - equivalent to pieces of fabric rubbing together or stray radio waves) to ignite the mixture.

Ignition of Gas

As the gravel is thrown into the tank by the rock slinger, it has the potential to create a spark by striking against metal inside the tank or against the gravel in the tank. The spark could ignite the sudden release of a plume of gas if hydrogen concentration exceeds the LFL. The probability of these events occurring at the same instant is low. At this time, it cannot be ruled out that the hydrogen concentration in the gas plume will exceed the LFL. The time it would take for the plume to diffuse and drop the hydrogen concentration to below the LFL by dilution from the ventilation system depends on the size and concentration of the plume, which cannot be accurately estimated at this time. Therefore, it may be assumed that the plume occurs and ignites.

The probability of the plume igniting could be reduced substantially by using wet sand or soil and possibly grout as fill instead of gravel.

Loss of Containment

The pressure necessary to cause failure in a SST varies from 76 kPa (11 psi) for a 3,800,000-L (1,000,000-gal) tank to 97 kPa (14 psi) for a 1,900,000-L (500,000-gal) tank (Julyk 1994). The pressure necessary to cause failure in a DST is 410 kPa (60 psi) because it has a steel liner. The pressure generated by the ignited plume is dependent on the plume size, head space, heat transfer, and ventilation. A plume of flammable gas (16 m^3 [570 ft^3]) sufficiently concentrated, if ignited, will cause an overpressure of 100 kPa (15 psi), which is more than enough to collapse the dome of a SST (Fox-Stepnewski 1994). For the DST, 100 kPa (15 psi) may not breach the dome but would blow out the HEPA filters. These potential overpressures do not take into account the 42-in. risers that penetrate the tank dome, which would absorb some of the pressure from a deflagration.

Additional saltwell pumping of the SSTs is expected to reduce the probability of hydrogen burps by removing liquids, which tend to trap gases in the saltcake. Additional saltwell pumping also would be expected to remove organic materials, such as complexants, which degrade to form flammable gases. The risk of a plume burn could also be reduced by filling the 25 Watchlist tanks last. It has been shown in tank waste that hydrogen generation rates drop by about one-half every 15 years. By waiting approximately 15 years to fill the 25 Watchlist tanks, the hydrogen generation rate of these tanks would drop by about 50 percent.

Source-term for SST Dome Collapse

It was conservatively assumed that all radiological and chemical contaminants in the headspace are available for release. The collapse of a portion of the dome and overburden compresses the vapor in the headspace as it descends, enhancing the vapor release rate by sudden pressure difference. Assuming a respirable concentration of contaminants in the headspace of 100 mg/m^3, a liquid SpG of 1.5, and a headspace volume of 1,000 m^3, the potential source-term contribution from the headspace release was calculated as follows:

$$(100\ mg/m^3) \cdot (1\ g/L\ 1{,}000\ mg) \cdot (1\ L/1{,}000\ g) \cdot (1{,}000\ m^3) \cdot (1/1.5) = 1.8E\text{-}02\ L\ (1.8E\text{-}02\ gal).$$

It was assumed that gravel fill takes place after saltwell pumping that has reduced the liquid in the SSTs to less than 0.5 percent. It was conservatively assumed the surface was dry and crumbly and the MAR was 2,500 L (660 gal). It was postulated that the fall of the objects generated a substantial air movement to suspend a fraction the MAR.

Assuming the respirable release fraction to be 2.0E-03, the potential source-term contribution from entrainment was calculated as follows:

$$(2{,}500\ L) \cdot (2.0E\text{-}03) = 5.0\ L\ (1.3\ gal).$$

It was postulated that prevailing winds resuspend a respirable fraction of the MAR (2,500 L [660 gal]). A respirable release fraction of 4.0E-05/hr for 24 hours was assumed. The potential source-term contribution from resuspension was calculated as follows:

$$(2{,}500\ L) \cdot (4.0E\text{-}05/hr) \cdot (24\ hr) = 2.4\ L\ (0.6\ gal).$$

The combined source-term of the potential SST accident is calculated as follows:

$$(0.07\ L) + (5.0\ L) + (2.4\ L) = 7.5\ L\ (2.0\ gal).$$

Source-term for the DSTs

For the DSTs, a consequence analysis was performed (LANL 1995) based on a dome space loading of 0.39 L (0.10 gal) in the vapor space plus 3.30 L (0.87 gal) entrained by the deflagration. It was assumed that the HEPA filter was destroyed by the pressure pulse generated by the ignited gases. The amount of material on the filter was assumed to be

0.45 L (0.12 gal). Therefore, the amount of inventory released from the tank would be 4.14 L (1.09 gal). The bounding source-term or respirable amount released from a DST and made airborne was 2.0 L (0.5 gal) for tank 241-SY-101 (LANL 1995).

E.4.3. 3 .2 Probability of the Event

The probability of a plume burn is assumed to be a likely event due to the gas pockets that exist in the waste and the available ignition source. However, the magnitude of the deflagration is uncertain. It is more likely that the gas burn would be small and would not have sufficient energy to blow out the HEPA filters or breach the tank. It is therefore assumed to be an extremely unlikely event, and for the purpose of this analysis, a probability of 1E-04 is used to calculate the point estimates.

E.4.3. 3 .3 Radiological Consequence for Tank Dome Collapse

The tank dome collapse would be bounding so the radiological dose to the receptors was calculated from the source-term for the SST by the GENII computer code (Napier et al. 1988) using the methodology previously discussed in Section E.1.1.6. The results (Shire et al. 1995 and Jacobs 1996) are summarized in Table E.4.3. 6 .

Table E.4.3.6 Dose Consequence for Tank Dome Collapse Due to Deflagration

E.4.3. 3 .4 Radiological Cancer Risk for Tank Dome Collapse

All 10 workers and the MEI noninvolved worker potentially would receive a lethal dose. The LCFs and LCF point estimate risk were calculated for the receptors and presented in Table E.4.3. 7 .

Table E.4.3.7 Latent Cancer Fatality Risk from Tank Dome Collapse Due to Deflagration

In the bounding scenario all 10 workers would die from a lethal dose . T he calculations show there would be 11 LCFs attributed to the exposure to the noninvolved workers and 2 LCFs to the general public if the accident occurred. In the nominal scenario there would be no LCF.

E.4.3. 3 .5 Chemical Consequences of Tank Dome Collapse

The chemical exposure to the receptors from the postulated accident was calculated in Appendix A of the accident data package (Shire et al. 1995 and Jacobs 1996) and summarized in the exposure column in Tables E.4.3.8 and E.4.3.9 for the nominal and bounding toxic effects, respectively, and Tables E.4.3.10 and E.4.3.11 for the nominal and bounding corrosive/irritant effects, respectively. The tables compare the concentration of postulated chemical releases to acute exposure criteria (ERPGs) discussed in Section 1.1.7.

Table E.4.3.8 Comparison of Nominal Chemical Concentrations to Toxic Concentration Limits for Tank Dome Collapse

Table E.4.3.9 Comparison of Bounding Chemical Concentrations to Toxic Concentrations Limits for Tank Dome Collapse

Table E.4.3.10 Comparison of Nominal Chemical Concentrations to Corrosive/Irritant Concentration Limits for Tank Dome Collapse

Table E.4.3.11 Comparison of Bounding Chemical Concentrations to Corrosive/Irritant Concentration Limits for Tank Dome Collapse

Under bounding conditions, chemical impacts were not evaluated for the MEI worker because all workers would receive a lethal radiation dose, as discussed previously.

Toxic Impact from Chemical Exposure

Under nominal conditions (Table E.4.3.8), the cumulative acute hazard ratio for the MEI worker was 2.64E+00 for ERPG-1, indicating that only mild transient effects would be expected. For the MEI noninvolved worker, the cumulative acute health hazard was 2.59E+00 for ERPG-3, indicating the potential for irreversible health effects that could be life threatening. This acute hazard ratio was primarily attributable to TOC (approximately 84 percent of the total hazard ratio). The TOC is assumed to be equivalent in toxicity to tributylphosphate which is the most acutely toxic constituent of the organic analytes identified. Tributylphosphate was used as a surrogate because an inventory of the various chemicals that make up the TOC class is not available. The cumulative acute hazard ratio, for the nearest noninvolved worker population consisting of 335 workers located 290 m (950 ft) away, was less than 1.0 for all ERPGs, suggesting that no acute health effects would be expected.

Under bounding conditions (Table E.4.3.9), the cumulative hazard ratios for the MEI and nearest noninvolved worker (335 workers located 290 m [950 ft] away) were 2.15E+03 and 7.80E+00 for ERPG-3, respectively. These ratios were primarily attributable to:

- Uranium (approximately 47 percent of the total hazard ratio);
- Oxalate (approximately 24 percent of the total hazard ratio); and
- Mercury (approximately 13 percent of the total hazard ratio).

This exceedance of the ERPG-3 criterion for the nearest noninvolved worker population would not be expected to result in irreversible health effects or place these workers in a life-threatening situation for the following reasons.

- ERPG-3 is defined as a concentration in which a receptor can be exposed for 1 hour without irreversible health effects. Because the Hanford Site has an in-place emergency response plan designed to evacuate workers within 1 hour of an accident, workers would be expected to evacuate their location and move to an area where potential exposures would be well below ERPG-3. Therefore, this worker population would not be exposed to airborne concentrations that would be either life threatening or result in irreversible health effects.
- The estimated air concentrations of chemicals as a result of this accident were based on very conservative meteorology, which results in movement of a plume directly toward the worker population at a relatively slow rate with minimal wind dispersion. If less conservative meteorological parameters were used, wind dispersion would cause the estimated air concentrations of chemicals to be substantially less, and the ERPG-3 criterion would not be exceeded.
- Only the bounding toxic chemical evaluation exceeded ERPG-3, while the nominal evaluation was well below 1.00E+00 for ERPG-3, suggesting that the noninvolved worker population would not receive an exposure that would result in any permanent health effects.

The cumulative acute hazard ratio for the next nearest noninvolved worker population, composed of 1,500 people and located 1,780 (5,840 ft) away, was 2.15 for ERPG-2, indicating that reversible acute health effects would be expected. The cumulative acute hazard ratio for the MEI general public was 1.76E+00 for ERPG-2, indicating that reversible acute health effects would be expected.

Corrosive/Irritant Impact from Chemical Exposure

Under nominal conditions (Table E.4.3.10), the cumulative acute hazard ratios for the MEI worker, MEI noninvolved worker and nearest noninvolved worker (335 workers at 290 m [950 ft]) were 2.47E+01, 5.10E+02 and 1.85E+00, respectively for ERPG-3, indicating the potential for irreversible health effects that could be life threatening. These ratios were almost entirely attributable to sodium which was assumed to be equivalent to sodium hydroxide in corrosive/irritant effects. This exceedance of the ERPG-3 criterion for the nearest noninvolved worker population would not be expected to result in irreversible health effects or place these workers in a life-threatening situation for the following reasons.

- ERPG-3 is defined as a concentration in which a receptor can be exposed for 1 hour without irreversible health effects. Because the Hanford Site has an in-place emergency response plan designed to evacuate workers within

1 hour of an accident, workers would be expected to evacuate their location and move to an area where potential exposures would be well below ERPG-3. Therefore, this worker population would not be exposed to airborne concentrations that would be either life threatening or result in irreversible health effects.

- The estimated air concentrations of chemicals as a result of this accident were based on very conservative meteorology, which results in movement of a plume directly toward the worker population at a relatively slow rate with minimal wind dispersion. If less conservative meteorological parameters were used, wind dispersion would cause the estimated air concentrations of chemicals to be substantially less, and the ERPG-3 criterion would not be exceeded.
- Only the bounding toxic chemical evaluation exceeded ERPG-3, while the nominal evaluation was well below 1.00E+00 for ERPG-3, suggesting that the noninvolved worker population would not receive an exposure that would result in any permanent health effects.

For the next nearest noninvolved worker population (1,500 workers at 1,780 [5,840 ft]), the cumulative acute hazard ratio was 1.20 for ERPG-1, indicating that only mild irreversible irritant effects would be anticipated. For the MEI general public, the cumulative acute hazard ratio was less than 1.0 for all ERPGs and no acute health effects would be expected.

Under bounding conditions (Table E.4.3.11), the cumulative acute hazard ratios for the MEI noninvolved worker and nearest noninvolved worker (335 workers at 290 m [950 ft]) were 7.31E+02 and 2.65, respectively for ERPG-3, indicating the potential for irreversible health effects that could be life threatening. These acute hazard ratios were primarily attributable to:

- Sodium (approximately 83 percent of the total hazard ratio); and
- Calcium (approximately 10 percent of the total hazard ratio).

As discussed previously, this exceedance of the ERPG-3 criterion would not be expected to result in irreversible or life threatening health effects.

For the next nearest noninvolved worker and MEI general public, the cumulative acute hazard ratios were 1.74 and 1.42, respectively for ERPG-1, indicating that only mild, transient irritant effects would be expected.

Under both nominal and bounding conditions, the probability of a seismic event is 1.00E-04.

E.4.3.4 Beyond Design Basis Accidents

The beyond design basis accident is a seismic event resulting in the collapse of a SST. In the event of a 0.43 g earthquake, a SST could potentially collapse (LANL 1995). This event is not dependent on the remediation alternative but has the same annual frequency regardless of the alternative that is chosen. The length of time unremediated waste would remain in tanks that have not been backfilled would vary depending on the alternative and would affect the probability of the event. The probability of the event is the product of the annual frequency of the earthquake and the number of years the waste remains untreated in the unstabilized tanks.

At smaller annual frequencies, larger earthquakes could occur resulting in greater destruction and larger numbers of LCF to the onsite and offsite populations. In addition to population exposures from the collapsed SSTs, the impact to other Hanford Site facilities and operations would potentially add to the chemical and radiological risk. This would be a severe earthquake that would cause catastrophic structural damage in the Tri-Cities and the Hanford Site with expected extensive loss of life. There would be injuries and fatalities resulting from collapsed buildings and homes, fires, and traffic accidents. However, this section evaluates the radiological and chemical impacts resulting from the collapse of one SST.

E.4.3.4.1 Source-Term Development

It was conservatively assumed that the radiological and chemical contaminants in the headspace are available for release. The collapse of a portion of the dome and overburden compresses the vapor in the headspace as it descends, enhancing the vapor release rate by a sudden pressure difference. Assuming for each tank a respirable concentration of contaminants in the headspace of 100 mg/m^3, a liquid SpG of 1.5, and a headspace volume of 1,000 m^3 (Shire et al. 1995 and Jacobs 1996), the potential source-term contribution from the headspace release was calculated as follows:

$$(100\ mg/m^3) \cdot (1\ g/1{,}000\ mg) \cdot (1\ L/1{,}000\ g) \cdot (1{,}000\ m^3) \cdot (1/1.5) = 6.67E\text{-}02\ L\ (1.8E\text{-}02\ gal).$$

It was conservatively assumed that the liquids had been pumped from the tanks so that the tanks contained only solids and the MAR was 2,500 L for each tank. It was postulated that the fall of the dome and overburden generated an air movement sufficient to suspend a fraction of the MAR. Assuming the respirable release fraction to be 2.0E-03 (Shire et al. 1995 and Jacobs 1996), the potential source-term contribution was calculated as follows:

$$(2{,}500\ L) \cdot (2.0E\text{-}03) = 5.0\ L\ (1.3\ gal).$$

It was postulated that prevailing winds resuspend a respirable fraction of the MAR (2,500 L [660 gal]). A respirable release fraction of 4.0E-05/hr for 24 hours was assumed. The potential source-term contribution from resuspension was calculated as follows:

$$(2{,}500\ L) \cdot (4.0E\text{-}05/hr) \cdot (24\ hr) = 2.4\ L\ (0.6\ gal).$$

The combined source-term for the acute release is calculated as follows:

$$(6.67E\text{-}02\ L) + (5.00E{+}00\ L) + (2.4\ L) = 7.4\ L\ (2.0\ gal).$$

E.4.3.4.2 Probability of a Beyond Design Basis Earthquake

This earthquake has a calculated annual exceedance frequency of approximately 1.40E-04 (WHC 1996b). The probability for this scenario based on 12 years of operation was therefore estimated to be 1.7E-03.

E.4.3.4.3 Radiological Consequences from a Beyond Design Basis Earthquake

The radiological dose to the receptors from the previous source-term was calculated by the GENII computer code (Napier et al. 1988) using the methodology previously discussed in Section E.1.1.6. The results are presented in Table E.4.3.12.

Table E.4.3.12 Dose Consequence from Seismic Event

E.4.3.4.4 Radiological Cancer Risk from a Beyond Design Basis Earthquake

The LCFs and LCF point estimate risk are presented in Table E.4.3.13.

Table E.4.3.13 Latent Cancer Fatality Risk from Seismic Event

In the bounding scenario, all 10 workers would potentially receive a fatal dose and assumably die directly after the exposure. There would also be 10 LCFs attributed to the exposure to the noninvolved workers and two LCFs to the general public if the accident occurred. The nominal scenario calculations show there would be no LCFs.

E.4.3.4.5 Chemical Consequences from a Beyond Design Basis Earthquake

Potential acute hazards associated with a beyond design basis earthquake are identical to those summarized in Tables E.2.2.16 (toxic chemicals, nominal conditions), E.2.2.17 (toxic chemicals, bounding conditions), E.2.2.18 (corrosive/irritant chemicals, nominal conditions) and E.2.2.19 (corrosive/irritant chemicals, bounding conditions) for the No Action alternative.

Under bounding conditions, chemical impacts were not evaluated for the MEI worker because all workers would receive a lethal radiation dose, as described previously.

Toxic Impact from Chemical Exposure

Under nominal conditions (Table E.2.2.16), the cumulative acute hazard ratio for the MEI worker was 2.64E+00 for ERPG-1, indicating that only mild transient effects would be expected. For the MEI noninvolved worker, the cumulative acute health hazard was 2.59E+00 for ERPG-3, indicating the potential for irreversible health effects that could be life threatening. This acute hazard ratio was primarily attributable to TOC (approximately 84 percent of the total hazard ratio). The TOC is assumed to be equivalent in toxicity to tributylphosphate, which is the most acutely toxic constituent of the organic analytes identified. Tributylphosphate was used as a surrogate because an inventory of the various chemicals that make up the TOC class is not available. The cumulative acute hazard ratio for the nearest noninvolved worker population consisting of 335 workers located 290 m (950 ft) away was less than 1.0 for all ERPGs, suggesting that no acute health effects would be expected.

Under bounding conditions (Table E.2.2.17), the cumulative hazard ratios for the MEI and nearest noninvolved worker (335 workers located 290 m [950 ft] away) were 2.15E+03 and 7.80E+00 for ERPG-3, respectively. These ratios were primarily attributable to:

- Uranium (approximately 47 percent of the total hazard ratio);
- Oxalate (approximately 24 percent of the total hazard ratio); and
- Mercury (approximately 13 percent of the total hazard ratio).

This exceedance of the ERPG-3 criterion for the nearest noninvolved worker population would not be expected to result in irreversible health effects or place these workers in a life-threatening situation for the following reasons.

- ERPG-3 is defined as a concentration in which a receptor can be exposed for 1 hour without irreversible health effects. Because the Hanford Site has an in-place emergency response plan designed to evacuate workers within 1 hour of an accident, workers would be expected to evacuate their location and move to an area where potential exposures would be well below ERPG-3. Therefore, this worker population would not be exposed to airborne concentrations that would be either life threatening or result in irreversible health effects.
- The estimated air concentrations of chemicals as a result of this accident were based on very conservative meteorology, which results in movement of a plume directly toward the worker population at a relatively slow rate with minimal wind dispersion. If less conservative meteorological parameters were used, wind dispersion would cause the estimated air concentrations of chemicals to be substantially less, and the ERPG-3 criterion would not be exceeded.
- Only the bounding toxic chemical evaluation exceeded ERPG-3, while the nominal evaluation was well below 1.00E+00 for ERPG-3, suggesting that the noninvolved worker population would not receive an exposure that would result in any permanent health effects.

The cumulative acute hazard ratio for the next nearest noninvolved worker population, composed of 1,500 people and located 1,780 m (5,840 ft) away, was 2.15E+00 for ERPG-2, indicating that reversible acute health effects would be expected. The cumulative acute hazard ratio for the MEI general public was 1.76E+00 for ERPG-2, indicating that reversible acute health effects would be expected.

Corrosive/Irritant Impact from Chemical Exposure

Under nominal conditions (Table E.2.2.18), the cumulative acute hazard ratios for the MEI worker, MEI noninvolved worker and nearest noninvolved worker (335 workers at 290 m [950 ft]) were 2.47E+01, 5.10E+02 and 1.85E+00, respectively, for ERPG-3, indicating the potential for irreversible health effects that could be life threatening. These ratios were almost entirely attributable to sodium, which was assumed to be equivalent to sodium hydroxide in corrosive/irritant effects. As discussed previously, this exceedance of the ERPG-3 criterion would not be expected to result in irreversible or life threatening health effects. For the next nearest noninvolved worker population, (1,500 workers at 1,780 m [5,840 ft]), the cumulative acute hazard ratio was 1.20E+00 for ERPG-1, indicating that only mild irreversible irritant effects would be anticipated. For the MEI general public, the cumulative acute hazard ratio was less than 1.0 for all ERPGs, and no acute health effects would be expected.

Under bounding conditions (Table E.2.2.19), the cumulative acute hazard ratios for the MEI noninvolved worker and nearest noninvolved worker (335 workers at 290 m [950 ft]) were 7.31E+02 and 2.65E+00, respectively for ERPG-3, indicating the potential for irreversible health effects that could be life threatening. These acute hazard ratios were primarily attributable to:

- Sodium (approximately 83 percent of the total hazard ratio); and
- Calcium (approximately 10 percent of the total hazard ratio).

As discussed previously, this exceedance of the ERPG-3 criterion would not be expected to result in irreversible or life threatening health effects.

For the next nearest noninvolved worker, and MEI general public, the cumulative acute hazard ratios were 1.74E+00 and 1.42E+00, respectively, for ERPG-1, indicating that only mild, transient irritant effects would be expected.

Under both nominal and bounding conditions, the probability of a seismic event is 1.68E-03.

E.4.3.5 Occupation Injuries, Illnesses, and Fatalities from Operations

The number of operation personnel to support the In Situ Fill and Cap alternative is summarized as follows:

- Continued operations - 2.39E+04 person-years; and
- Treatment operations - 1.51E+03 person-years.

Therefore, there would be a total of 2.54E+04 person-years for the In Situ Fill and Cap alternative. The total recordable injuries and illnesses lost workday cases and fatalities were calculated as follows:

Total Recordable Cases = (2.54E+04 person-years) · (2.2E+00 incidences/100 person-years) = 5.59E+02

Lost Workday Cases = (2.54E+04 person-years) · (1.1E+00 incidences/100 person-years) = 2.80E+02

Fatalities = (2.54E+04 person-years) · (3.2E-03 fatalities/100 person-years) = 8.13E-01

E.4.4 POST-REMEDIATION ACCIDENT

E.4.4.1 Deflagration in Storage Tank

After the tanks have been filled with gravel, the dome sealed off, and the Hanford Barrier placed over the tank farms, it was postulated that hydrogen builds up in the tank, reaches the LFL, and ignites. The probable sequence of events is that the tank would breach and possibly the asphalt layer in the Hanford Barrier would crack allowing an increased movement of the residual tank waste into the groundwater from increased infiltration. An explosion that could breach the dome, displace 23 m (7 ft) of overburden, and displace an additional 50 m (15 ft) of the Hanford Barrier, is considered to be incredible. For this event to occur, the following conditions must exist:

- Flammable gases must be generated from the waste;
- The concentration of the flammable gas must exceed the lower flammability limit;
- There must be an ignition source; and
- The deflagration would have to generate enough energy to breach the tank and crack the asphalt liner.

Generation of Flammable Gas

All 177 waste tanks produce flammable gases at the molecular level such as hydrogen, ammonia, and methane along with nitrous oxide (an oxidizer) due to radiolysis, organic degradation, and corrosion.

Gas Concentration

Gases generated from the residual tank waste would diffuse and accumulate in the voids within the gravel and the tank headspace created by the waste settling under the pressure of the fill. If the hydrogen is not allowed to escape from the tank through leaks or cracks in the tank, the hydrogen concentration will continue to increase as long as the potential for radiolysis, organic degradation, or corrosion exists.

It has been shown in tank waste that hydrogen generation rates may drop by approximately one-half every 15 years. Therefore, the gas concentration potential could be reduced by allowing the tanks to vent for 100 years (during institutional controls) through vent pipes passing up through the Hanford Barrier. The vents could then be sealed off. Allowing the tanks to vent for 100 years would reduce the probability of hydrogen reaching the LFL in the tank. Hydrogen gas concentration could be retarded by placing catalytic recombiners in the tank that would recombine hydrogen and oxygen. The buildup of hydrogen could be mitigated over the long-term by engineering permanent measures to allow the gas to escape into the atmosphere. This may include cutting small openings in the tanks domes and the asphalt layer within the Hanford Barrier.

Ignition of Gas

If the gas concentrations in the tank manage to exceed the LFL, the ignition sources are limited. Possible ignition sources would include a lightning strike, an earthquake, or heat produced by reactions taking place in the materials remaining in the tank. If the gas was ignited, the propagation of the burn through the gravel is dependent on the size of the voids in the gravel matrix. Flames will not propagate in a porous material if the pore size is less than a critical value.

Consequences of Deflagration

The probable sequence of events is that the tank would breach and possibly the asphalt layer in the Hanford Barrier would crack allowing an increased leaching of the residual tank waste into the groundwater.

Consequences of Gas Building Up Under the Asphalt Barrier

If the hydrogen gas generated in the tanks was able to permeate from the tank through leaks and cracks, it could potentially build up under the asphalt layer of the Hanford Barrier if the permeation rate through the asphalt is slower than the rate in which it reaches the asphalt. Because hydrogen is highly diffusible, it is extremely unlikely that this would be the case. However, if hydrogen did build up under the asphalt layer, the worst credible consequences would result in the asphalt cracking allowing an increased movement of the residual tank waste into the groundwater. This event could be mitigated by placing catalytic recombiners under the asphalt that would recombine hydrogen and oxygen or venting the asphalt layer.

E.4.4.2 Seismic Induced Rupture of Stabilized Tanks

An evaluation was performed to determine if displacement on a fault could increase exposure to the waste after remediation was completed. For this to occur, a capable fault (a fault on which displacement can occur) would have to intersect one or more tanks and cause displacement equal to the thickness of the soil cover on the tank and the Hanford Barrier, a total of 6.4 m (21 ft).

The seismicity of the area was studied extensively when the area was a potential candidate site for a potential geologic repository (Rockwell 1983). This report concludes that earthquakes in the central Columbia Plateau indicate the stress regime that exists today has been relatively unchanged for more than 14 million years, and no change of this stress regime is anticipated over the next 100,000 years. Deformation was in progress in the late Grande Ronde time (approximately 14.5 million years before present) and continued at an average low rate of uplift (vertical strain) from 14.5 to 10.5 million years before present as determined from the aerial and thickness distribution of basalt flows.

Strain appears to be concentrated in steeply dipping strata and on major structures. New first-order structures do not appear to have developed in the Quaternary, nor are they anticipated to develop in the next 10,000 to 100,000 years (Rockwell 1983).

Seismicity in the central Columbia Plateau is confined to a thin, 2.6-m (8.5-ft) crust and is characterized by temporally and spatially limited swarms of low magnitude (magnitude 3.5), shallow (0.6-m [2-ft]) earthquakes that may be characteristic of brittle deformation in basalt.

Earthquakes in the central Columbia Plateau presently are not associated with mapped geologic faults, nor in a manner that suggests the presence of unmapped faults. Swarms have occurred on the flanks of the Saddle Mountains, a first-order structure which is faulted, but the events do not correspond with mapped faults. However, swarms also have occurred elsewhere where there are no mapped geologic structures. Some small alignments are indicated by the migration of swarm events in the Saddle Mountains.

An average displacement rate of 0.03 to 0.06 mm/yr (0.0012 to 0.0024 in/yr) was calculated. While a fault model has been assumed, this estimate could represent the total deformation associated with a wider zone north and south of the crest of the Saddle Mountains structure.

Because the average deformation rate of the region is 0.06 mm/yr (0.0024 in./yr), there would be 0.6 m (2 ft) of deformation in 10,000 years. This is much less than the 6.4 m (21 ft) of cover over the tanks. Therefore, even if all displacement in the region were concentrated on one fault and that fault intersected a tank, there would be only 0.6 m (2 ft) of displacement over 10,000 years and therefore, waste would not be displaced to the surface. The tanks would most likely crack, allowing increased infiltration to the groundwater.

E.4.5 SUMMARY OF ACCIDENTS

The potential consequences from nonradiological and nonchemical accidents that include occupational and transportation impacts are summarized in Table E.4.5.1 The LCFs associated with representative accidents for each component of the alternative are summarized in Table E.4.5.2 along with the probability of the accident. The chemical hazards associated with representative accidents for each component of the alternative are summarized in Table E.4.5.3. The chemical hazard is expressed as exceedance of the ERPG threshold values.

Table E.4.5.1 Summary of Potential Nonradiological/Nonchemical Accident Consequences

Table E.4.5.2 Summary of Potential Radiological Accident Consequences

Table E.4.5.3 Chemical Exposures Resulting from Potential Operations and Transportation Accidents

E.5.0 IN SITU VITRIFICATION ALTERNATIVE

This section analyses the risk resulting from potential accidents associated with the In Situ Vitrification alternative. The In Situ Vitrification alternative would involve the following activities:

- Construct and operate a tank farm confinement facility that would support in situ vitrification of tank waste including MUSTs;
- Waste transfer system upgrade construction (W-314);
- Continue evaporating liquid through the 242-A Evaporator;
- Fill tank voids with sand prior to in situ vitrification; and
- Construct Hanford Barriers over tank farms.

E.5.1 CONSTRUCTION ACCIDENTS

The construction activities associated with the In Situ Vitrification alternative are discussed in Appendix B of the EIS. It should be noted there are no radiological or chemical consequences associated with construction accidents. Occupational injuries, illnesses, and fatalities resulting from potential construction accidents are calculated as follows.

The number of construction personnel was estimated at an average 2.25E+04 person-years (Jacobs 1996). The total recordable injuries and illnesses, lost workday cases, and fatalities during the 22 years of construction were calculated using the incidence rates from Table E.1.2.1 as follows:

Total Recordable Cases = (2.25E+04 person-years) · (9.75E+00 incidences/100 person-years) = 2.19E+03

Lost Workday Cases = (2.25E+04 person-years) · (2.45E+00 incidences/100 person-years) = 5.51E+02

Fatalities = (2.25E+04 person-years) · (3.2E-03 fatalities/100 person-years) = 7.19E-01

E.5.2 TRANSPORTATION ACCIDENTS

Transporting activities associated with this alternative include:

- Transporting construction material from offsite for the tank farms confinement facility and the waste transfer system upgrade;
- Transporting earthen material from onsite borrow site for the waste transfer system upgrade and to fill tank voids;
- Transporting aggregate from onsite borrow site for concrete;
- Transporting process chemicals for off-gas treatment;
- Transporting earthen material from onsite borrow site for the Hanford Barrier; and
- Employees commuting to work each day.

E.5.2.1 Radiological Cancer Risk

All operations would be conducted within established operating parameters for the tanks and would not involve transporting radioactive materials by container. Therefore, there would be no radiological cancer risks from transportation.

E.5.2.2 Chemical Exposure

Anhydrous ammonia would be transported to the Hanford Site by rail to support the off-gas treatment process. The toxicological impacts of anhydrous ammonia were analyzed in Green (Green 1995). The annual quantities and annual shipments for in situ vitrification are similar to those analyzed in Green (Green 1995). The toxicological impacts are summarized in Table E.5.2.1. Table E.5.2.1 compares the concentration of the postulated chemical release to exposure limits discussed in Section 1.1.7. The general public exposure to anhydrous ammonia would exceed the ratio of exposure to ERPG-3 by 1.24E+01 and propane would exceed the ratio of exposure to ERPG-1 by 3.67E+00 for corrosive/irritant chemicals. Based on the magnitude of the anhydrous ammonia exceedance, potential lethal effects would be expected.

Table E.5.2.1 Comparison of Chemical Concentrations to Corrosive/Irritant Concentration Limits for the In Situ Vitrification Alternative

E.5.2.3 Occupational Injuries and Fatalities

Truck and Rail Transportation

Injuries and fatalities resulting from direct impact of transportation accidents are analyzed in this subsection. Truck and rail transportation activities to transport materials and supplies to the Site for this alternative were estimated in the In Situ Vitrification engineering data package (WHC 1995f) and are summarized in Table E.5.2.2. The total distance was calculated by multiplying the number of trips by the round-trip distance.

Table E.5.2.2 Summary of Transportation Activities for the In Situ Vitrification Alternative

The number of fatalities and injuries were calculated by multiplying the total distance traveled in each zone, shown in Table E.5.2.3, by the appropriate unit risk factors shown in Table E.1.3.1. The distance traveled in the population zones were calculated using the methodology previously discussed in Section E.1.3. The expected injuries and fatalities resulting from transportation accidents associated with the In Situ Vitrification alternative are summarized in Table E.5.2.4.

Table E.5.2.3 Distance Traveled in Population Zones for the In Situ Vitrification Alternative

Table E.5.2.4 Injuries/Fatalities Resulting from Truck and Rail Transportation Accidents for the In Situ Vitrification Alternative

Employee Traffic

In addition to transporting materials and supplies to and from the Hanford Site by truck and rail, Site workers and other personnel required to perform the various activities would be driving to the Site in their vehicles. The total person-years to perform the activities was estimated at 4.88E+04 (Jacobs 1996).

Each person was assumed to work 260 days of the year. The round-trip distance traveled to work from the Tri-City area was estimated at 140 km (87 mi) with an estimated 1.35 passengers per vehicle (DOE 1994a). The total personnel vehicle distance was therefore calculated to be 1.32E+09 km (8.2E+09 mi).

To calculate the expected number of injuries and fatalities resulting from vehicle accidents, the injury/fatality rates discussed in Section 1.3 were used. The expected number of injuries and fatalities resulting from employee vehicle accidents was calculated as follows:

Injuries = (1.32E+09 km) · (7.14E-7 injuries/km) = 9.40E+02

Fatalities = (1.32E+09 km) · (8.98E-9 fatalities/km) = 1.18E+01

Cumulative Transportation Injuries and Fatalities

The cumulative nonradiological and nontoxicological injuries and fatalities incurred as a direct result of traffic accident impacts is the sum of the truck, rail, and employee vehicle accidents. The results are summarized in Table

E.5.2.5.

Table E.5.2.5 Cumulative Injuries and Fatalities from Traffic Impacts for the In Situ Vitrification Alternative

E.5.3 OPERATION ACCIDENTS

The potential exists for accidents resulting from operation activities. The operations are discussed in Appendix B.

This analysis separates and analyzes operations according to the following modes of operation:

- Continued operations - These operations have been previously discussed in the No Action alternative;
- Treatment - An off-gas hood would be placed over the tank and a confinement enclosure installed over the hood and the tank farm. The void space in the tank is filled with sand from the Hanford Site. Electrodes are positioned in the tank and surrounding the tank, and the tank waste is vitrified in place as well as the soil column surrounding the tanks.
- Hanford Barrier - After vitrification, the off-gas hood and confinement enclosure are removed. A multi-layer barrier of earthen material would be placed over the tank farms.

The dominant accident scenarios analyzed in the following subsections were selected from the Accident Screening Table (Table E.5.3.1). The accidents listed in Table E.5.3.1 were taken from the accident analysis data package (Shire et al. 1995 and Jacobs 1996). The methodology of screening was previously discussed in Section 1.1.2.

Table E.5.3.1 Accident Screening Table for the In Situ Vitrification Alternative

E.5.3.1 Continued Operation Accidents - Tank Waste Transfers

The dominant continued operations accident during tank waste transfers is the "mispositioned jumper accident" previously discussed in the No Action alternative in Section E.2.2.1 and is summarized as follows:

Source-term - The source-term resulting from a spray release in Section E.2.2.1.1 was calculated to be 52 L (14 gal).

Probability - The frequency of a mispositioned jumper in Section E.2.2.1.2 was 1.1E-02 per year. The In Situ Vitrification alternative is based on 1 6 years of operations. Therefore, the probability for the In Situ Vitrification alternative was calculated to be 1.8E-01.

Radiological Consequences - The radiological consequences presented in Table E.2.2.2 are reproduced in Table E.5.3.2.

Table E.5.3.2 Dose Consequence from Mispositioned Jumper

Radiological Cancer Risk - The LCFs calculated in Section E.2.2.1.4 are the same for the In Situ Vitrification alternative; however, the LCF point estimate risk is not the same due to the difference in probabilities. The LCFs and the LCF risk are calculated in Table E.5.3.3. The bounding calculations show all 10 workers would potentially receive a fatal dose and assumably die directly after the exposure if the accident occurred. Approximately seven noninvolved workers would receive fatal cancers and there would be two fatal cancers to the general public. The nominal scenario calculations show there would be no LCFs.

Table E.5.3.3 Latent Cancer Fatality Risk from Mispositioned Jumper

Chemical Consequences

Potential acute hazards associated with a mispositioned jumper are identical to those summarized in Tables E.2.2.4 (toxic chemicals, nominal conditions), E.2.2.5 (toxic chemicals, bounding conditions), E.2.2.6 (corrosive/irritant chemicals, nominal conditions) and E.2.2.7 (corrosive/irritant chemicals, bounding conditions) for the No Action alternative.

Toxic Impact from Chemical Exposure

Under nominal conditions (Table E.2.2.4), the cumulative acute hazard ratios for the MEI worker, MEI noninvolved worker and MEI general public were less than 1.0, indicating that no adverse acute health effects would be expected for these three receptors. Under bounding conditions (Table E.2.2.5), the MEI worker was not evaluated because death would occur from exposure to radionuclides. The cumulative acute hazard ratio for the MEI noninvolved worker was 5.36E+00 for ERPG-2, indicating that reversible acute health effects would be expected. This acute hazard ratio was primarily attributable to mercury (approximately 89 percent of the overall hazard ratio). No adverse acute health effects were predicted for the MEI general public under bounding conditions.

Corrosive/Irritant Impact from Chemical Exposure

Under nominal conditions (Table E.2.2.6), the cumulative acute hazard ratio for the MEI worker was 2.70E+00 for ERPG-3, indicating the potential for irreversible health effects that could be life-threatening. This acute hazard ratio was almost entirely attributable to sodium assumed to be equivalent to sodium hydroxide in corrosive/irritant effects. For the MEI noninvolved worker, the cumulative acute hazard ratio for ERPG-1 was 3.00E+00, indicating that only mild reversible irritant effects would be expected. No acute health impacts were predicted for the MEI general public under nominal conditions. Under bounding conditions (Table E.2.2.7), the MEI worker was not evaluated because death would occur from exposure to radionuclides. For the MEI noninvolved worker, the cumulative acute hazard ratio for ERPG-1 was 4.36, indicating that only mild reversible irritant effects would be expected. No acute health impacts were predicted for the MEI general public under bounding conditions.

Under both nominal and bounding conditions, the probability of a mispositioned jumper is 1.76E-01.

Corrosive/Irritant Impact from Chemical Exposure

For the MEI worker, the cumulative ratio of exposure to ERPG-2 values for corrosive/irritant chemicals was 1.93E+00, exceeds 1.0, and would be indicative of reversible acute effects. The MEI noninvolved worker cumulative ratio of exposure to ERPG-1 values was 3.10E+00. This acute hazard index is primarily attributable to sodium hydroxide (approximately 90 percent of the total hazard). The acute hazard index for the MEI general public was less than 1.0 for ERPG-1 comparisons and would not be indicative of acute effects.

E.5.3.2 Continued Operations Accident - Waste Storage Tanks

The dominant accident is a hydrogen deflagration in a waste storage tank previously discussed in the No Action alternative in Section E.2.2.2.1 and is summarized as follows:

Source-term - The source-term resulting from a hydrogen deflagration in Section E.2.2.2.1 was calculated to be 2.4 L (0.6 gal).

Probability - The frequency of the hydrogen deflagration in a waste storage tank in Section E.2.2.2.2 was estimated to be 7.2E-03 per year. The probability of the scenario based on 16 years of operation was therefore estimated to be 1.2E-01.

Radiological Consequences - The radiological consequences presented in Table E.2.2.8 are reproduced in Table E.5.3.4.

Radiological Cancer Risk - The LCFs calculated in Section E.2.2.2.4 are reproduced in Table E.5.3.5.

In the bounding scenario all 10 workers would potentially receive a fatal dose and would assumably die directly after the exposure. There would also be 10 LCFs attributed to the exposure to the noninvolved workers and 2 LCFs to the general public if the accident occurred. The nominal scenario calculations show there would be no LCFs.

Table E.5.3.4 Dose Consequence from Hydrogen Deflagration in Waste Storage Tank

Table E.5.3.5 Latent Cancer Fatality Risk from Hydrogen Deflagration in Waste Storage Tank

Chemical Consequences

Potential acute hazards associated with a hydrogen burn in a waste storage tank are identical to those summarized in Tables E.2.2.10 (toxic chemicals, nominal conditions), E.2.2.11 (toxic chemicals, bounding conditions), E.2.2.12 (corrosive/irritant chemicals, nominal conditions) and E.2.2.13 (corrosive/irritant chemicals, bounding conditions) for the No Action alternative.

Under bounding conditions, chemical impacts were not evaluated for the MEI worker because all workers would receive a lethal radiation dose as discussed previously.

Toxic Impact from Chemical Exposure

Under nominal conditions (Table E.2.2.10), the cumulative acute hazard ratio for the MEI worker was 1.57E+00 for ERPG-2, indicating that reversible acute health effects would be expected. This acute hazard ratio was primarily attributable to TOC (approximately 87 percent of the overall ERPG-2 ratio). The TOC is assumed to be equivalent in toxicity to tributylphosphate, which is the most acutely toxic constituent of the organic analytes identified. Tributylphosphate was used as a surrogate because an inventory of the various chemicals that make up the TOC class is not available. For the MEI noninvolved worker, the cumulative acute hazard ratio for ERPG-3 was 9.38E+00, indicating the potential for irreversible health effects that could be life-threatening. This acute hazard ratio was also primarily attributable to TOC (approximately 90 percent of the overall ERPG-3 ratio). However, the MEI noninvolved worker is a hypothetical worker assumed to be located 100m (330 ft) from the source area. The first anticipated noninvolved worker population is located 290 m (950 ft) from the source area and had no cumulative acute hazard ratios greater than 1.0 for any of the ERPGs, indicating that no acute health effects would be expected for the nearest noninvolved worker population. Likewise, no acute health effects were predicted for the MEI general public under nominal conditions.

Under bounding conditions (Table E.2.2.11), the cumulative acute hazard ratio for the MEI noninvolved worker was 4.54E+02 for ERPG-3, indicating the potential for irreversible health effects that could be life-threatening. This acute hazard ratio is primarily attributable to:

- Oxalate (approximately 37 percent of the total hazard ratio);
- Beryllium (approximately 13 percent of the total hazard ratio);
- Cadmium (approximately 14 percent of the total hazard ratio);
- Uranium (approximately 12 percent of the total hazard ratio); and
- TOC (approximately 8 percent of the total hazard ratio).

As discussed previously, this is a hypothetical receptor located 100m (330 ft) from the source. The cumulative acute hazard ratio for the nearest noninvolved worker population located 290 m (950 ft) from the source was 1.65E+00 for ERPG-3, indicating the potential for irreversible health effects that could be life threatening for 335 workers. This hazard ratio was attributable to the same toxic chemicals listed above. This exceedance of the ERPG-3 criterion for the nearest noninvolved worker population would not be expected to result in irreversible health effects or place these workers in a life-threatening situation for the following reasons.

- ERPG-3 is defined as a concentration in which a receptor can be exposed for 1 hour without irreversible health effects. Because the Hanford Site has an in-place emergency response plan designed to evacuate workers within 1 hour of an accident, workers would be expected to evacuate their location and move to an area where potential exposures would be well below ERPG-3. Therefore, this worker population would not be exposed to airborne concentrations that would be either life threatening or result in irreversible health effects.
- The estimated air concentrations of chemicals as a result of this accident were based on very conservative meteorology, which results in movement of a plume directly toward the worker population at a relatively slow rate with minimal wind dispersion. If less conservative meteorological parameters were used, wind dispersion

would cause the estimated air concentrations of chemicals to be substantially less, and the ERPG-3 criterion would not be exceeded.
- Only the bounding toxic chemical evaluation exceeded ERPG-3, while the nominal evaluation was well below 1.00E+00 for ERPG-3, suggesting that the noninvolved worker population would not receive an exposure that would result in any permanent health effects.

The next nearest noninvolved worker population is located 1,780 m (5,840 ft) from the source and contains 1,500 workers. The cumulative acute hazard ratio was less than 1.0 for all ERPGs, indicating that no acute health effects would be expected for this population of workers. No acute health impacts were predicted for the MEI general public.

Corrosive/Irritant Impact from Chemical Exposure

Under nominal conditions (Table E.2.2.12), the cumulative acute hazard ratio for the MEI worker was 3.82E+00 for ERPG-3, indicating the potential for irreversible corrosive/irritant effects that could be life threatening. For the MEI noninvolved worker, the cumulative acute hazard ratio for ERPG-3 was 7.89E+01 and would indicate irreversible corrosive/irritant effects that could be life threatening for this hypothetical receptor. This hazard ratio was primarily attributable to sodium, which was assumed to be equivalent to sodium hydroxide in corrosive/irritant effects. For the nearest noninvolved worker population (290 m [950 ft]) composed of 335 workers, the cumulative acute hazard ratio for ERPG-1 was 1.38E+01, indicating that only mild reversible effects would be expected. No acute health impacts were predicted for the MEI general public under nominal conditions.

Under bounding conditions (Table E.2.2.13), the cumulative acute hazard ratio for the MEI noninvolved worker was 1.91E+02 for ERPG-3, indicating irreversible health effects that could be life threatening for this hypothetical receptor. This hazard ratio was primarily attributable to :

- Sodium as sodium hydroxide (approximately 75 percent of the total hazard ratio);
- Chromium (approximately 14 percent of the total hazard ratio); and
- Calcium (approximately 6 percent of the total hazard ratio).

For the nearest noninvolved worker population (290 m [950 ft]) composed of 335 workers, the cumulative acute hazard ratio was 1.74E+00 for ERPG-2, indicating that reversible acute effects would be expected. No acute health impacts were predicted for the MEI general public under nominal conditions.

Under both nominal and bounding conditions, the probability of a hydrogen deflagration event in a waste storage tank is 1.15E-01.

E.5.3. 3 Treatment Accidents

Types of potential accidents with treatment include ventilation failure, fire, explosion, exothermic reactions, mechanical impacts, and criticality. From Table E.5.3.1 the credible accident identified as having the highest risk was Accident 4.4.4.3, "rupture off-gas duct". It was postulated that a double-ended break occurs in the off-gas line between the off-gas hood and the off-gas treatment facility. The initiating event was postulated to be an earthquake.

E.5.3. 3 .1 Scenario and Source-term Development for Off-Gas Rupture

Most radionuclides are volatilized at the vitrifying temperature and would be drawn into the off-gas hood and ventilation system by exhaust flow. The break would result in a release directly to the environment without the benefit of off-gas treatment.

The normal off-gas flow was calculated to be 300 m^3/min. A respirable airborne concentration of 200 mg/m^3 was assumed in the tank headspace because of the high temperature associated with the vitrification process. The airborne concentration was assumed to be less than 30 percent radioactive waste because of the presence of a frit. An SpG of 1.00 was assumed for the tank waste. The exposure time was assumed to be 16 hours. The respirable source-term was calculated as follows:

$$(300\ m^3/min) \cdot (200\ mg/m^3) \cdot (30\ percent) \cdot (1.0E\text{-}06\ L/mg) \cdot (960\ min) = 17\ L\ (4.6\ gal)$$

E.5.3. 3 .2 Probability of Off-Gas Duct Rupture

The annual exceedance frequency of the earthquake was assumed to be 1.00E-03 in the accident data package (Shire et al. 1995 and Jacobs 1996). The probability for this scenario based on 16 years of operation was therefore estimated to be 1.6E-02.

E.5.3. 3 .3 Radiological Consequence of Off-Gas Duct Rupture

The radiological dose to the receptors from the previous source-term was calculated by the GENII computer code (Napier et al. 1988) using the methodology previously discussed in Section 1.1.6. The results are presented in Table E.5.3. 6 .

Table E.5.3.6 Dose Consequence for Off-Gas Duct Rupture

E.5.3. 3 .4 Radiological Cancer Risk for Off-Gas Duct Rupture

The LCFs and the LCF point estimate risk were calculated for the receptors and presented in Table E.5.3. 7 .

Table E.5.3.7 Latent Cancer Fatality Risk from Off-Gas Duct Rupture

In the bounding scenario all 10 workers would potentially receive a fatal dose and assumably die directly after the exposure. T he calculations show there would be 36 fatal cancers to the noninvolved worker population and 5 fatal cancers to the general public population attributable to this exposure if the accident occurred. The nominal scenario calculations show there would be no LCFs.

E.5.3. 3 .5 Chemical Consequences of Off-Gas Duct Rupture

The chemical exposure to the receptors from the postulated accident was calculated in Appendix A of the accident data package (Shire et al. 1995 and Jacobs 1996) and summarized in the exposure column in Tables E.5.3.8 and E.5.3.9 for the nominal and bounding toxic effects, respectively, and Tables E.5.3.10 and E.5.3.11 for the nominal and bounding corrosive/irritant effects, respectively. The tables compare the concentration of postulated chemical releases to acute exposure criteria (ERPGs) discussed in Section 1.1.7.

Table E.5.3.8 Comparison of Nominal Chemical Concentrations to Toxic Concentration Limits for Off Gas Duct Rupture - DST Solids

Table E.5.3.9 Comparison of Bounding Chemical Concentrations to Toxic Concentration Limits for Off Gas Duct Rupture - DST Solids

Table E.5.3.10 Comparison of Nominal Chemical Concentrations to Corrosive/Irritant Concentration Limits for Off Gas Duct Rupture - DST Solids

Table E.5.3.11 Comparison of Bounding Chemical Concentrations to Corrosive/Irritant Concentration Limits for Off Gas Duct Rupture - DST Solids

Under bounding conditions, chemical impacts were not evaluated for the MEI worker because all workers would receive a lethal radiation dose, as discussed previously.

Toxic Impact from Chemical Exposure

Under nominal conditions (Table E.5.3.8), the cumulative acute hazard ratios for the MEI worker, MEI noninvolved worker and MEI general public were less than 1.0, indicating that no adverse acute health effects would be expected for these three receptors. Under bounding conditions (Table E.5.3.9), the cumulative acute hazard ratio for the MEI noninvolved worker was 1.54 for ERPG-1, indicating that only mild, transient acute health effects would be expected. No adverse acute health effects were predicted for the MEI general public under bounding conditions.

Corrosive/Irritant Impact from Chemical Exposure

Under nominal conditions (Table E.5.3.10), the cumulative acute hazard ratio for the MEI worker was 1.09 for ERPG-2, indicating that reversible acute irritant effects would be expected. This acute hazard ratio was almost entirely attributable to sodium assumed to be equivalent to sodium hydroxide in corrosive/irritant effects. For the MEI noninvolved worker and general public, the cumulative acute hazard ratios were less than 1.0 for all ERPGs, indicating that no acute health effects would be expected for these populations

Under bounding conditions (Table E.5.3.11), the cumulative acute hazard ratio for the MEI noninvolved worker was 1.16 for ERPG-1, indicating that only mild transient irritant effects would be expected. No acute health impacts were predicted for the MEI general public under bounding conditions.

Under both nominal and bounding conditions, the probability of an offgas duct rupture is 1.60E-02.

E.5.3.4 Beyond Design Basis Accidents

The beyond design basis accident is a seismic event resulting in the collapse of a SST. In the event of a 0.43 g earthquake, a SST could potentially collapse (LANL 1995). This event is not dependent on the remediation alternative but has the same annual frequency regardless of the alternative that is chosen. The length of time unremediated waste would remain in tanks that have not been backfilled would vary depending on the alternative and would affect the probability of the event. The probability of the event is the product of the annual frequency of the earthquake and the number of years the waste remains untreated in the unstabilized tanks.

At smaller annual frequencies, larger earthquakes could occur resulting in greater destruction and larger numbers of LCF to the onsite and offsite populations. In addition to population exposures from the collapsed SSTs, the impact to other Hanford Site facilities and operations would potentially add to the chemical and radiological risk. This would be a severe earthquake that would cause catastrophic structural damage in the Tri-Cities and the Hanford Site with expected extensive loss of life. There would be injuries and fatalities resulting from collapsed buildings and homes, fires, and traffic accidents. However, this section evaluates the radiological and chemical impacts resulting from the collapse of one SST.

E.5.3.4.1 Source-Term Development

It was conservatively assumed that the radiological and chemical contaminants in the headspace are available for release. The collapse of a portion of the dome and overburden compresses the vapor in the headspace as it descends, enhancing the vapor release rate by sudden a pressure difference. Assuming for each tank a respirable concentration of contaminants in the headspace of 100 mg/m^3, a liquid SpG of 1.5, and a headspace volume of 1,000 m^3 (Shire et al. 1995 and Jacobs 1996), the potential source-term contribution from the headspace release was calculated as follows:

$$(100\ \text{mg/m}^3) \cdot (1\ \text{g}/1{,}000\ \text{mg}) \cdot (1\ \text{L}/1{,}000\ \text{g}) \cdot (1{,}000\ \text{m}^3) \cdot (1/1.5) = 6.67\text{E-}02\ \text{L}\ (1.8\text{E-}02\ \text{gal}).$$

It was conservatively assumed that the liquids had been pumped from the tanks so that the tanks contained only solids and the MAR was 2,500 L (660 gal) for each tank. It was postulated that the fall of the dome and overburden generated an air movement sufficient to suspend a fraction of the MAR. Assuming the respirable release fraction to be 2.0E-03 (Shire et al. 1995 and Jacobs 1996), the potential source-term contribution was calculated as follows:

$$(2{,}500\ \text{L}\ [660\ \text{gal}]) \cdot (2.0\text{E-}03) = 5.0\ \text{L}\ (1.3\ \text{gal}).$$

It was postulated that prevailing winds resuspend a respirable fraction of the MAR (2,500 L [660 gal]). A respirable release fraction of 4.0E-05/hr for 24 hours was assumed. The potential source-term contribution from resuspension was calculated as follows:

(2,500 L [660 gal]) · (4.0E-05/hr) · (24 hr) = 2.4 L (0.6 gal).

The combined source-term for the acute release is calculated as follows:

(6.67E-02 L) + (5.00E+00 L) + (2.4 L) = 7.4 L (2.0 gal).

E.5.3.4.2 Probability of a Beyond Design Basis Earthquake

This earthquake has a calculated annual exceedance frequency of approximately 1.40E-04 (WHC 1996b). The probability for this scenario based on 16 years of operation was therefore estimated to be 2.2E-03.

E.5.3.4.3 Radiological Consequences from a Beyond Design Basis Earthquake

The radiological dose to the receptors from the previous source-term was calculated by the GENII computer code (Napier et al. 1988) using the methodology previously discussed in Section E.1.1.6. The results are presented in Table E.5.3.12.

Table E.5.3.12 Dose Consequence from Seismic Event

E.5.3.4.4 Radiological Cancer Risk from a Beyond Design Basis Earthquake

The LCFs and LCF point estimate risk are presented in Table E.5.3.13.

Table E.5.3.13 Latent Cancer Fatality Risk from Seismic Event

In the bounding scenario, all 10 workers would potentially receive a fatal dose and assumably die directly after the exposure. There would also be 10 LCFs attributed to the exposure to the noninvolved workers and two LCFs to the general public if the accident occurred. The nominal scenario calculations show there would be no LCFs.

E.5.3.4.5 Chemical Consequences from a Beyond Design Basis Earthquake

Potential acute hazards associated with a beyond design basis earthquake are identical to those summarized in Tables E.2.2.16 (toxic chemicals, nominal conditions), E.2.2.17 (toxic chemicals, bounding conditions), E.2.2.18 (corrosive/irritant chemicals, nominal conditions) and E.2.2.19 (corrosive/irritant chemicals, bounding conditions) for the No Action alternative.

Under bounding conditions, chemical impacts were not evaluated for the MEI worker because all workers would receive a lethal radiation dose, as described previously.

Toxic Impact from Chemical Exposure

Under nominal conditions (Table E.2.2.16), the cumulative acute hazard ratio for the MEI worker was 2.64E+00 for ERPG-1, indicating that only mild transient effects would be expected. For the MEI noninvolved worker, the cumulative acute health hazard was 2.59E+00 for ERPG-3, indicating the potential for irreversible health effects that could be life threatening. This acute hazard ratio was primarily attributable to TOC (approximately 84 percent of the total hazard ratio). The TOC is assumed to be equivalent in toxicity to tributylphosphate, which is the most acutely toxic constituent of the organic analytes identified. Tributylphosphate was used as a surrogate because an inventory of the various chemicals that make up the TOC class is not available. The cumulative acute hazard ratio for the nearest noninvolved worker population consisting of 335 workers located 290 m (950 ft) away was less than 1.0 for all

ERPGs, suggesting that no acute health effects would be expected.

Under bounding conditions (Table E.2.2.17), the cumulative hazard ratios for the MEI and nearest noninvolved worker (335 workers located 290 m (950 ft) away) were 2.15E+03 and 7.80E+00 for ERPG-3, respectively. These ratios were primarily attributable to:

- Uranium (approximately 47 percent of the total hazard ratio);
- Oxalate (approximately 24 percent of the total hazard ratio); and
- Mercury (approximately 13 percent of the total hazard ratio).

This exceedance of the ERPG-3 criterion for the nearest noninvolved worker population would not be expected to result in irreversible health effects or place these workers in a life-threatening situation for the following reasons.

- ERPG-3 is defined as a concentration in which a receptor can be exposed for 1 hour without irreversible health effects. Because the Hanford Site has an in-place emergency response plan designed to evacuate workers within 1 hour of an accident, workers would be expected to evacuate their location and move to an area where potential exposures would be well below ERPG-3. Therefore, this worker population would not be exposed to airborne concentrations that would be either life threatening or result in irreversible health effects.
- The estimated air concentrations of chemicals as a result of this accident were based on very conservative meteorology, which results in movement of a plume directly toward the worker population at a relatively slow rate with minimal wind dispersion. If less conservative meteorological parameters were used, wind dispersion would cause the estimated air concentrations of chemicals to be substantially less, and the ERPG-3 criterion would not be exceeded.
- Only the bounding toxic chemical evaluation exceeded ERPG-3, while the nominal evaluation was well below 1.00E+00 for ERPG-3, suggesting that the noninvolved worker population would not receive an exposure that would result in any permanent health effects.

The cumulative acute hazard ratio for the next nearest noninvolved worker population, composed of 1,500 people and located 1,780 m (5,840 ft) away, was 2.15E+00 for ERPG-2, indicating that reversible acute health effects would be expected. The cumulative acute hazard ratio for the MEI general public was 1.76E+00 for ERPG-2, indicating that reversible acute health effects would be expected.

Corrosive/Irritant Impact from Chemical Exposure

Under nominal conditions (Table E.2.2.18), the cumulative acute hazard ratios for the MEI worker, MEI noninvolved worker and nearest noninvolved worker (335 workers at 290 m [950 ft]) were 2.47E+01, 5.10E+02 and 1.85E+00, respectively, for ERPG-3, indicating the potential for irreversible health effects that could be life threatening. These ratios were almost entirely attributable to sodium, which was assumed to be equivalent to sodium hydroxide in corrosive/irritant effects. As discussed previously, this exceedance of the ERPG-3 criterion would not be expected to result in irreversible or life threatening health effects. For the next nearest noninvolved worker population, (1,500 workers at 1,780 m [5,840 ft]), the cumulative acute hazard ratio was 1.20E+00 for ERPG-1, indicating that only mild irreversible irritant effects would be anticipated. For the MEI general public, the cumulative acute hazard ratio was less than 1.0 for all ERPGs, and no acute health effects would be expected.

Under bounding conditions (Table E.2.2.19), the cumulative acute hazard ratios for the MEI noninvolved worker and nearest noninvolved worker (335 workers at 290 m [950 ft]) were 7.31E+02 and 2.65E+00, respectively for ERPG-3, indicating the potential for irreversible health effects that could be life threatening. These acute hazard ratios were primarily attributable to:

- Sodium (approximately 83 percent of the total hazard ratio); and
- Calcium (approximately 10 percent of the total hazard ratio).

As discussed previously, this exceedance of the ERPG-3 criterion would not be expected to result in irreversible or life threatening health effects.

For the next nearest noninvolved worker, and MEI general public, the cumulative acute hazard ratios were 1.74E+00 and 1.42E+00, respectively, for ERPG-1, indicating that only mild, transient irritant effects would be expected.

Under both nominal and bounding conditions, the probability of a seismic event is 2.25E-03.

E.5.3.5 Occupational Injuries and Fatalities from Operations

The number of operation personnel was estimated at approximately 2.64E+04 person-years (Jacobs 1996). The total recordable injuries and illnesses, lost workday cases, and fatalities were calculated as follows:

Total Recordable Cases = (2.64E+04 person-years) · (2.2E+00 incidences/100 person-years) = 5.80E+02

Lost Workday Cases = (2.64E+04 person-years) · (1.1E+00 incidences/100 person-years) = 2.90E+02

Fatalities = (2.64E+04 person-years) · (3.2E-03 fatalities/100 person-years) =8.43E-01

E.5.4 POST-REMEDIATION ACCIDENT

E.5.4.1 Deflagration in Storage Tank

After the tank waste was vitrified in-place and the organics destroyed in the process, the probability of a tank generating enough hydrogen to exceed the LFL is considered to be incredible.

E.5.4.2 Seismic Induced Rupture of Stabilized Tanks

As discussed in Section E.4.4.2, displacement on a fault resulting in an airborne release of the waste after remediation is considered incredible. The tanks would most likely crack, allowing increased infiltration to the groundwater.

E.5.5 SUMMARY OF ACCIDENTS

The potential consequences from nonradiological and nonchemical accidents that include occupational and transportation impacts are summarized in Table E.5.5.1. The LCFs associated with representative accidents for each component of the alternative are summarized in Table E.5.5.2 along with the probability of the accident. The chemical hazards associated with representative accidents for each component of the alternative are summarized in Table E.5.5.3. The chemical hazard is expressed as an exceedance of the ERPG threshold values.

Table E.5.5.1 Summary of Potential Nonradiological/Nonchemical Accident Consequences

Table E.5.5.2 Summary of Potential Radiological Accident Consequences

Table E.5.5.3 Chemical Exposures Resulting from Potential Operations and Transportation Accidents

E.6.0 EX SITU INTERMEDIATE SEPARATIONS ALTERNATIVE

The Ex Situ Intermediate Separations alternative for tank waste would involve constructing and operating vitrification and support facilities, low-level vitrified waste burial vaults, and transfer lines from the tank farms and T Plant to the vitrified facilities. This alternative would also involve transporting retrieved tank waste to a vitrification facility and vehicle traffic of the personnel required to support the alternative. This section analyzes the construction, operation, and transportation risks associated with this alternative.

E.6.1 CONSTRUCTION ACCIDENTS

The potential exists for accidents resulting from construction activities. The construction activities are outlined in Appendix B of the EIS. It should be noted there are no radiological or chemical consequences associated with construction accidents. Occupational injuries, illnesses, and fatalities resulting from potential construction accidents are calculated as follows.

The number of construction personnel was estimated at an average 3.11E+04 person-years (Jacobs 1996). The number of total recordable injuries and illnesses, lost workday cases, and fatalities were calculated using the incidence rates from Table E.1.2.1 as follows:

Total Recordable Cases = (3.11E+04 person-years) · (9.75E+00 incidences/100 person-years) = 3.03E+03

Lost Workday Cases = (3.11E+04 person-years) · (2.45E+00 incidences/100 person-years) = 7.61E+02

Fatalities = (3.11E+04 person-years) · (3.2E-03 fatalities/100 person-years) = 9.94E-01

E.6.2 TRANSPORTATION ACCIDENTS

Under the Ex Situ Intermediate Separations alternative, Hanford Site tank waste would be stabilized by vitrification. The vitrified HLW would be shipped to onsite storage and the LAW would be buried in vaults on the Hanford Site. These waste streams would be transported by pipeline, truck, and rail. In addition to transporting the waste, construction materials and process chemicals would be transported to the Hanford Site by truck and rail. This alternative would also be supported by a work force of employees that would commute to work each day.

E.6.2.1 Radiological Cancer Risk

Radiological exposures resulting from accidents were analyzed using RADTRAN 4 (Neuhauser-Kanipe 1992). Exposures resulting from accidents from the following transportation activities were included in the analysis.

- Transporting residual waste from the SSTs to the processing facility by truck; and
- Transporting waste from MUSTs to the processing facility by truck.

The analysis addressed radiological accident impacts as an integrated population risk (i.e., accident frequencies times consequences integrated over the entire shipping campaign) using RADTRAN 4 and a maximum credible accident using GENII computer codes (Napier et al. 1988).

The population doses were dependent on the accident probability, release quantities, atmospheric dispersion parameters, population distribution parameters, human uptake, and dosimetry models.

Radiological exposure to the MEI was calculated for a bounding scenario accident by GENII computer code (Green 1995). The public and worker dose calculated by GENII were dependent on the release quantities of radioactive material, release duration, receptor location, and meteorology.

E.6.2.1.1 Truck Transport of Retrieved Tank Waste

The receptor dose and LCF risk resulting from the accident analysis for retrieval of MUST waste and SST residuals is presented in Table E.6.2.1 for the integrated population and Table E.6.2.2 for the MEI worker and MEI general public.

Table E.6.2.1 Integrated Radiological Impact from Retrieval Transport Accidents

Table E.6.2.2 MEI Radiological Impact from Retrieval Transport Accidents

There would be no LCFs resulting from an accident while transporting retrieved waste on site.

E.6.2.2 Chemical Exposure

Chemicals transported to the Hanford Site to support the pretreatment and vitrification processes would have the greatest chemical impact. An analysis was performed to 1) identify the hazardous chemicals that could result in the largest toxicological impacts; and 2) evaluate the toxicological impacts of the maximum credible accidents involving the highest hazard chemicals (Green 1995). A preliminary screening analysis was performed to identify the chemicals representing the highest potential toxicological hazard. The highest hazard chemicals in terms of toxicity were determined to be nitric acid, sodium hydroxide, anhydrous ammonia, and dicyclopentadiene. The chemical concentrations resulting from the maximum credible accident at 100 m (330 ft) and the frequency of the accidents (Green 1995) are summarized in Table E.6.2.3.

Table E.6.2.3 Chemical Releases from Postulated Accidents for the Ex Situ Intermediate Separations Alternative

Table E.6.2.4 compares the respirable concentration of the postulated chemical releases to exposure limits discussed in Section E.1.1.7.

Table E.6.2.4 Comparison of Chemical Concentrations to Corrosive/Irritant Concentration Limits for the Ex Situ Intermediate Separations Alternative

Table E.6.2.4 shows the general public exposure to anhydrous ammonia would exceed the ratio of exposure to ERPG-3 by 1.24E+01 and sodium hydroxide would exceed the ratio of exposure to ERPG-1 by 2.45E+00 for corrosive/irritant chemicals. The magnitude of the anhydrous ammonia exceedance indicates potential lethal effects for the MEI general public.

E.6.2.3 Occupational Injuries and Fatalities

Truck and Rail Transportation

Injuries and fatalities resulting from direct impact of transportation accidents are analyzed in this subsection. Rail and truck transportation activities to transport materials and supplies to the Site for this alternative were estimated (WHC 1995j) and are summarized in Table E.6.2.5.

Table E.6.2.5 Summary of Transportation Activities for the Ex Situ Intermediate Separations Alternative

The number of injuries and fatalities were calculated by multiplying the total distance traveled in each zone shown in Table E.6.2.6 by the appropriate unit risk factors shown in Table E.1.3.1. The distance traveled in the population zones were calculated using the methodology previously discussed in Section E.1.3. The expected injuries and fatalities resulting from transportation accidents associated with the Ex Situ Intermediate Separations alternative are summarized in Table E.6.2.7.

Table E.6.2.6 Distance Traveled in Population Zones for the Ex Situ Intermediate Separations Alternative

Table E.6.2.7 Injuries and Fatalities Resulting from Truck and Rail Transportation Accidents for the Ex Situ Intermediate Separations Alternative

Employee Traffic

In addition to transporting materials and supplies to and from the Hanford Site by truck and rail, Site workers and other personnel required to perform the various activities would be driving to the site in their vehicles. The total person-years to perform the activities was estimated at 8.58E+04.

Each person was assumed to work 260 days of the year. The round-trip distance traveled to work from the Tri-Cities area was estimated at 140 km (87 mi) with an estimated 1.35 passengers per vehicle (DOE 1994a). The total employee vehicle distance was therefore calculated as follows:

(8.58E+04 person-years) · (260 days/year) · (140 km/day) · (1/1.35) = 2.31E+09 km (1.44E+09 mi)

To calculate the expected number of injuries and fatalities resulting from vehicle accidents, the injury/fatality rates discussed in Section E.1.3 were used. The expected number of injuries and fatalities resulting from employee vehicle accidents were calculated as follows:

Injuries = (2.31E+09 km) · (7.14E-07 injuries/km) = 1.65E+03

Fatalities = (2.31E+09 km) · (8.98E-09 fatalities/km) = 2.08E+01

Cumulative Transportation Injuries and Fatalities

The cumulative nonradiological and nontoxicological injuries and fatalities incurred as a direct result of traffic accident impacts are the sum of the truck and rail transport and employee vehicle accidents. The results are summarized in Table E.6.2.8.

Table E.6.2.8 Cumulative Injuries and Fatalities from Traffic Impacts for the Ex Situ Intermediate Separations Alternative

E.6.3 OPERATION ACCIDENTS

Operations are discussed in Appendix B. The operations are separated and analyzed according to the following modes of operation:

- Continued operations - Previously discussed in the No Action alternative.
- Retrieval operations - DST waste would be extracted from tanks using slurry pumping. Hydraulic sluicing would be used to remove SST waste. If hydraulic sluicing did not meet waste retrieval goals, robotic arm-based retrieval methods would be used. Pipelines would transfer waste from the tank farms to a pretreatment facility.
- Pretreatment - Pretreatment would consist of sludge washing and chemical processes to separate the waste into HLW and LAW streams. The solids in the tank would be washed to dissolve salts to the extent practical and those salts bearing liquid would be added to the supernatant stream going to Cs removal. The sludge remaining in the tanks would be washed to remove additional solids and to minimize the feed to the HLW vitrification facility.
- Treatment - LAW would be pumped into a LAW vitrification facility where it would be mixed with feed material and vitrified into glass. Vitrification is a high-temperature process where waste is blended with additives and fused into a glass-like form suitable for disposal. The HLW would be routed from a lag storage facility, where it would be temporarily stored before treatment, to a HLW vitrification facility where it would be mixed with feed material (such as glass formers) and then fused into glass.
- Disposal - The LAW glass would be placed into a near-surface retrievable disposal facility on the Hanford Site. A Hanford Barrier would be constructed over the retrievable LAW disposal site to inhibit migration of contaminants or intrusion by humans or animals. The high-level vitrification waste glass would be placed in

aboveground storage facility at the Hanford Site. It would then be shipped by rail to an offsite potential geologic repository for permanent disposal.

The potential for accidents exists during the operation of these activities. The dominant accident scenarios analyzed in the following subsections were selected from the Accident Screening Table (Table E.6.3.1). The methodology of the table was previously discussed in Section E.1.1.2.

Table E.6.3.1 Accident Screening Table for the Ex Situ Intermediate Separations Alternative

E.6.3.1 Routine Operation Accidents - Tank Waste Transfers

The dominant routine operations accident during tank waste transfer is the mispositioned jumper accident previously discussed in the No Action alternative in Section E.2.2.1 and summarized as follows:

Source-term - The source-term resulting from a spray release in Section E.2.2.1.1 was calculated to be 52 L (14 gal).

Probability - The frequency of a mispositioned jumper in Section E.2.2.1.2 was 1.1E-02 per year. The Ex Situ Intermediate Separations routine operation activity was based on 25 years of operations; therefore, the probability was calculated to be 2.8E-01.

Radiological Consequences - The radiological consequences presented in Table E.2.2.2 are reproduced in Table E.6.3.2.

Table E.6.3.2 Dose Consequence from Mispositioned Jumper

Radiological Cancer Risk - The LCFs calculated in Section E.2.2.1.4 are the same for the Ex Situ Intermediate Separations alternative. However, the LCF risk (point estimate) is not the same due to the difference in probabilities. The LCFs and the LCF risk are calculated in Table E.6.3.3.

Table E.6.3.3 Latent Cancer Fatality Risk from Mispositioned Jumper

The bounding calculations show all 10 workers would potentially receive fatal dose and assumably die directly after the exposure if the accident occurred. Approximately seven noninvolved workers would receive fatal cancers and two fatal cancers would be incurred to the general public. The nominal scenario calculations show there would be no LCFs.

Chemical Consequences

Potential acute hazards associated with a mispositioned jumper are identical to those summarized in Tables E.2.2.4 (toxic chemicals, nominal conditions), E.2.2.5 (toxic chemicals, bounding conditions), E.2.2.6 (corrosive/irritant chemicals, nominal conditions) and E.2.2.7 (corrosive/irritant chemicals, bounding conditions) for the No Action alternative.

Toxic Impact from Chemical Exposure

Under nominal conditions (Table E.2.2.4), the cumulative acute hazard ratios for the MEI worker, MEI noninvolved worker, and MEI general public were less than 1.0, indicating that no adverse acute health effects would be expected for these three receptors. Under bounding conditions (Table E.2.2.5), the MEI worker was not evaluated because death would occur from exposure to radionuclides. The cumulative acute hazard ratio for the MEI noninvolved worker was 5.36E+00 for ERPG-2, indicating that reversible acute health effects would be expected. This acute hazard ratio was primarily attributable to mercury (approximately 89 percent of the overall hazard ratio). No adverse acute health effects were predicted for the MEI general public under bounding conditions.

Corrosive/Irritant Impact from Chemical Exposure

Under nominal conditions (Table E.2.2.6), the cumulative acute hazard ratio for the MEI worker was 2.70E+00 for

ERPG-3, indicating the potential for irreversible health effects that could be life threatening. This acute hazard ratio was almost entirely attributable to sodium assumed to be equivalent to sodium hydroxide in corrosive/irritant effects. For the MEI noninvolved worker, the cumulative acute hazard ratio for ERPG-1 was 3.00E+00, indicating that only mild, reversible irritant effects would be expected. No acute health impacts were predicted for the MEI general public under nominal conditions. Under bounding conditions (Table E.2.2.7), the MEI worker was not evaluated because death would occur from exposure to radionuclides. For the MEI noninvolved worker, the cumulative acute hazard ratio for ERPG-1 was 4.36E+00, indicating that only mild reversible irritant effects would be expected. No acute health impacts were predicted for the MEI general public under bounding conditions.

Under both nominal and bounding conditions, the probability of a mispositioned jumper is 2.75E-01.

E.6.3.2 Continued Operations Accidents - Waste Storage Tanks

The dominant accident is a hydrogen deflagration in a waste storage tank previously discussed in the No Action alternative in Section E.2.2.2.1 and is summarized as follows.

Source-term - The source-term resulting from the fire in Section E.2.2.2.1 was calculated to be 2.4 L (0.6 gal).

Probability - The frequency of the hydrogen deflagration in a waste storage tank in Section E.2.2.2.2 was estimated to be 7.2E-03 per year. The probability of the scenario based on 25 years of operation was therefore estimated to be 1.8E-01.

Radiological Consequences - The radiological consequences presented in Table E.2.2.8 are reproduced in Table E.6.3.4.

Table E.6.3.4 Dose Consequence from Hydrogen Deflagration in Waste Storage Tank

Radiological Cancer Risk - The LCFs calculated in Section E.2.2.2.4 are the same for the Ex Situ Intermediate Separations alternative. However, the LCF risk (point estimate) is not the same due to the difference in probabilities. The LCR and the LCF risk are calculated in Table E.6.3.5.

Table E.6.3.5 Latent Cancer Fatality Risk from Hydrogen Deflagration in Waste Storage Tank

In the bounding all 10 workers would potentially receive a fatal dose and assumably die directly after the exposure. There would also be 10 LCFs attributed to the exposure to the noninvolved workers and 2 LCFs to the general public if the accident occurred. The nominal scenario calculations show there would be no LCFs.

Chemical Consequences

Potential acute hazards associated with a hydrogen burn in a waste storage tank are identical to those summarized in Tables E.2.2.10 (toxic chemicals, nominal conditions), E.2.2.11 (toxic chemicals, bounding conditions), E.2.2.12 (corrosive/irritant chemicals, nominal conditions) and E.2.2.13 (corrosive/irritant chemicals, bounding conditions) for the No Action alternative.

Under bounding conditions, chemical impacts were not evaluated for the MEI worker because all workers would receive a lethal radiation dose as discussed previously.

Toxic Impact from Chemical Exposure

Under nominal conditions (Table E.2.2.10), the cumulative acute hazard ratio for the MEI worker was 1.57E+00 for ERPG-2, indicating that reversible acute health effects would be expected. This acute hazard ratio was primarily attributable to TOC (approximately 87 percent of the overall ERPG-2 ratio). The TOC is assumed to be equivalent in toxicity to tributylphosphate, which is the most acutely toxic constituent of the organic analytes identified. Tributylphosphate was used as a surrogate because an inventory of the various chemicals that make up the TOC class is not available. For the MEI noninvolved worker, the cumulative acute hazard ratio for ERPG-3 was 9.38E+00, indicating the potential for irreversible health effects that could be life-threatening. This acute hazard ratio was also primarily attributable to TOC (approximately 90 percent of the overall ERPG-3 ratio) However, the MEI noninvolved worker is a hypothetical worker assumed to be located 100m (330 ft) from the source area. The first anticipated noninvolved worker population is located 290 m (950 ft) from the source area and had no cumulative acute hazard ratios greater than 1.0 for any of the ERPGs, indicating that no acute health effects would be expected for the nearest noninvolved worker population. Likewise, no acute health effects were predicted for the MEI general public under nominal conditions.

Under bounding conditions (Table E.2.2.11), the cumulative acute hazard ratio for the MEI noninvolved worker was 4.54E+02 for ERPG-3, indicating the potential for irreversible health effects that could be life-threatening. This acute hazard ratio is primarily attributable to:

- Oxalate (approximately 37 percent of the total hazard ratio);
- Beryllium (approximately 13 percent of the total hazard ratio);
- Cadmium (approximately 14 percent of the total hazard ratio);
- Uranium (approximately 12 percent of the total hazard ratio); and
- TOC (approximately 8 percent of the total hazard ratio).

As discussed previously, this is a hypothetical receptor located 100m (330 ft) from the source. The cumulative acute hazard ratio for the nearest noninvolved worker population located 290 m (950 ft) from the source was 1.65E+00 for ERPG-3, indicating the potential for irreversible health effects that could be life threatening for 335 workers. This hazard ratio was attributable to the same toxic chemicals listed above. This exceedance of the ERPG-3 criterion for the nearest noninvolved worker population would not be expected to result in irreversible health effects or place these workers in a life-threatening situation for the following reasons.

- ERPG-3 is defined as a concentration in which a receptor can be exposed for 1 hour without irreversible health effects. Because the Hanford Site has an in-place emergency response plan designed to evacuate workers within 1 hour of an accident, workers would be expected to evacuate their location and move to an area where potential exposures would be well below ERPG-3. Therefore, this worker population would not be exposed to airborne concentrations that would be either life threatening or result in irreversible health effects.
- The estimated air concentrations of chemicals as a result of this accident were based on very conservative meteorology, which results in movement of a plume directly toward the worker population at a relatively slow rate with minimal wind dispersion. If less conservative meteorological parameters were used, wind dispersion would cause the estimated air concentrations of chemicals to be substantially less, and the ERPG-3 criterion would not be exceeded.
- Only the bounding toxic chemical evaluation exceeded ERPG-3, while the nominal evaluation was well below 1.00E+00 for ERPG-3, suggesting that the noninvolved worker population would not receive an exposure that would result in any permanent health effects.

The next nearest noninvolved worker population is located 1,780 m (5,840 ft) from the source and contains 1,500 workers. The cumulative acute hazard ratio was less than 1.0 for all ERPGs, indicating that no acute health effects would be expected for this population of workers. No acute health impacts were predicted for the MEI general public.

Corrosive/Irritant Impact from Chemical Exposure

Under nominal conditions (Table E.2.2.12), the cumulative acute hazard ratio for the MEI worker was 3.82E+00 for ERPG-3, indicating the potential for irreversible corrosive/irritant effects that could be life threatening. For the MEI noninvolved worker, the cumulative acute hazard ratio for ERPG-3 was 7.89E+01 and would indicate irreversible corrosive/irritant effects that could be life threatening for this hypothetical receptor. This hazard ratio was primarily attributable to sodium, which was assumed to be equivalent to sodium hydroxide in corrosive/irritant effects. For the nearest noninvolved worker population (290 m [950 ft]) composed of 335 workers, the cumulative acute hazard ratio for ERPG-1 was 1.38E+01, indicating that only mild reversible effects would be expected. No acute health impacts were predicted for the MEI general public under nominal conditions.

Under bounding conditions (Table E.2.2.13), the cumulative acute hazard ratio for the MEI noninvolved worker was

1.91E+02 for ERPG-3, indicating irreversible health effects that could be life threatening for this hypothetical receptor. This hazard ratio was primarily attributable to:

- Sodium as sodium hydroxide (approximately 75 percent of the total hazard ratio);
- Chromium (approximately 14 percent of the total hazard ratio); and
- Calcium (approximately 6 percent of the total hazard ratio).

For the nearest noninvolved worker population (290 m [950 ft]) composed of 335 workers, the cumulative acute hazard ratio was 1.74E+00 for ERPG-2, indicating that reversible acute effects would be expected. No acute health impacts were predicted for the MEI general public under nominal conditions.

Under both nominal and bounding conditions, the probability of a hydrogen deflagration event in a waste storage tank is 1.80E-01.

E.6.3.3 Retrieval Accidents

The types of potential accidents associated with retrieval are leaks, sprays, ventilation failure, fire/deflagration, mechanical impacts, and criticality. From the Accident Screening Table (Table E.6.3.1), the accident within design basis identified as having the highest risk was Accident E.4.3.1.10, "loss of filtration."

A tank dome collapse analysis (Shire et al. 1995 and Jacobs 1996) concluded that the annual frequency of the event would be incredible depending on barrier configuration and administrative controls. The collapse of a tank dome would require a heavy vehicle on the dome. Large objects such as the tank 241-SY-101 mixer pump do not represent sufficient weight to cause damage to the tank dome because they are suspended from a support structure in the central pit. Mechanical barriers such as posts spaced closely together would prevent large vehicles from driving on top of the domes without removing the posts. Post removal would be administratively controlled through a controlled locking system. Failure of the barrier configuration and the administrative control system was calculated to be 1.0E-07/year.

E.6.3.3.1 Scenario and Source-term Development for Loss of Filtration

It was postulated that a ventilation heater failure could occur due to an electrical fault resulting in humid air plugging the HEPA filter and filter blowout. A condenser maintenance backflush error could also result in plugging the HEPA filter and filter blowout. Loss of both stages of filtration would allow an unfiltered release LPF of 1.00 for the bounding scenario.

The impact of the postulated accident during retrieval of tank waste would result in an airborne release of the radionuclides in the headspace of the tank. Assuming a respirable concentration of radionuclides in the headspace of 100 mg/m^3 (based on a partition fraction between liquid and aerosol of 1.0E-07), a liquid SpG of 1, and a headspace volume of 2,500 m^3, the potential source-term from the headspace release was calculated as follows:

$$(100\ \text{mg/m}^3) \cdot (2{,}500\ \text{m}^3) \cdot (1\ \text{g}/1{,}000\ \text{mg}) \cdot (1\ \text{L}/1{,}000\ \text{g}) \cdot (1) = 0.25\ \text{L}\ (0.066\ \text{gal}).$$

E.6.3.3.2 Probability of Loss of Filtration

The annual frequency of the event was calculated in the potential accident data package (Shire et al. 1995 and Jacobs 1996) as follows:

The failure rate of an electrically powered air heater was calculated to be 8.8E-03/yr based on an hourly failure rate of 1.0E-06. The HEPA filtration system would have a monitoring and alarm system that could detect the change in the differential pressure caused by a filter plug or filter blowout. This system was given a failure rate of 1.0E-03/yr. The annual frequency of this event was therefore calculated to be 8.8E-06. Based on 25 years of operation, the probability was calculated to be 2.2E-04.

E.6.3.3.3 Radiological Consequence from Loss of Filtration

The radiological dose to the receptors from the previous source-term was calculated by the GENII computer code (Napier et al. 1988) using the methodology previously discussed in Section E.1.1.6. The results (Shire et al. 1995 and Jacobs 1996) are summarized in Table E.6.3.6.

Table E.6.3.6 Dose Consequence from Loss of Filtration

E.6.3.3.4 Radiological Cancer Risk from Loss of Filtration

The LCFs and the LCF point estimate risk were calculated for the receptors and are presented in Table E.6.3.7.

Table E.6.3.7 Latent Cancer Fatality Risk from Loss of Filtration

In the bounding scenario all 10 workers would potentially receive a fatal dose and assumably die directly after the exposure. There would also be less than one LCF attributed to the exposure to the noninvolved workers and general public if the accident occurred. The nominal scenario calculations show there would be no LCFs.

E.6.3.3.5 Chemical Consequences from Loss of Filtration

The chemical exposure to the receptors from the postulated accident was calculated in Appendix A of the accident data package (Shire et al. 1995 and Jacobs 1996) and summarized in the exposure column in Tables E.6.3.8 and E.6.3.9 for the nominal and bounding toxic effects, respectively, and Tables E.6.3.10 and E.6.3.11 for the nominal and bounding corrosive/irritant effects, respectively. The tables compare the concentration of postulated chemical releases to acute exposure criteria (ERPGs) discussed in Section 1.1.7.

Table E.6.3.8 Comparison of Nominal Chemical Concentrations to Toxic Concentration Limits for Loss of Filtration

Table E.6.3.9 Comparison of Bounding Chemical Concentrations to Toxic Concentration Limits for Loss of Ventilation - SST Solids

Table E.6.3.10 Comparison of Nominal Chemical Concentrations to Corrosive/Irritant Concentration Limits for Loss of Filtration

Table E.6.3.11 Comparison of Bounding Chemical Concentrations to Corrosive/Irritant Concentration Limits for Loss of Filtration - SST Solids

Under bounding conditions, chemical impacts were not evaluated for the MEI worker because all workers would receive a lethal radiation dose, as discussed previously.

Toxic Impact from Chemical Exposure

Under nominal conditions (Table E.6.3.8) the cumulative acute hazard ratio for the MEI worker was less than 1.0 for all ERPGs, indicating that no adverse acute health effects would be expected. For the MEI noninvolved worker, the cumulative acute hazard ratio was 1.84 for ERPG-1, indicating that only mild, transient acute health effects would be expected. No acute health effects were predicted for the MEI general public under nominal conditions.

Under bounding conditions (Table E.6.3.9), the cumulative acute hazard ratio for the MEI noninvolved worker was 7.27E+01 for ERPG-3, indicating the potential for irreversible health effects that could be life-threatening. This acute hazard ratio is primarily attributable to:

- Uranium (approximately 48 percent of the total hazard ratio);
- Oxalate (approximately 24 percent of the total hazard ratio);

- Mercury (approximately 13 percent of the total hazard ratio); and
- TOC (approximately 7 percent of the total hazard ratio).

As discussed previously, this is a hypothetical receptor located 100m (330 ft) from the source. The cumulative acute hazard ratio for the nearest noninvolved worker population (335 workers) located 290 m (950 ft) from the source was 5.40E+00 for ERPG-2, indicating that reversible acute health effects would be expected. No acute health impacts were predicted for the MEI general public.

Corrosive/Irritant Impact from Loss of Filtration

Under nominal conditions (Table E.6.3.10), the cumulative acute hazard ratio for the MEI worker was 2.11E+00 for ERPG-2, indicating that reversible corrosive/irritant effects would be expected. For the MEI noninvolved worker, the cumulative acute hazard ratio for ERPG-3 was 1.72E+01 and would indicate irreversible corrosive/irritant effects that could be life threatening for this hypothetical receptor. This hazard ratio was primarily attributable to sodium which was assumed to be equivalent to sodium hydroxide in corrosive/irritant effects. For the nearest noninvolved worker population (290 m [950 ft]) composed of 335 workers, the cumulative acute hazard ratio for ERPG-1 was 3.02, indicating that only mild, transient irritant effects would be expected. No acute health impacts were predicted for the MEI general public under nominal conditions.

Under bounding conditions (Table E.6.3.11), the cumulative acute hazard ratio for the MEI noninvolved worker was 2.47E+01 for ERPG-3, indicating irreversible health effects that could be life threatening for this hypothetical receptor. This hazard ratio was primarily attributable to :

- Sodium as sodium hydroxide (approximately 82 percent of the total hazard ratio); and
- Calcium (approximately 9 percent of the total hazard ratio).

For the nearest noninvolved worker population (290 m [950 ft]) composed of 335 workers, the cumulative acute hazard ratio was 4.38 for ERPG-1, indicating that only mild, transient irritant effects would be expected. No acute health impacts were predicted for the MEI general public under nominal conditions.

Under both nominal and bounding conditions, the probability of a loss of filtration event is 2.20E-04 for the MEI worker, MEI noninvolved worker and MEI general public.

E.6.3.4 Pretreatment

Types of potential accidents associated with pretreatment are spills, sprays, and explosions. From the Accident Screening Table (Table E.6.3.1), the design basis accident identified as having the highest risk was a pressurized spray release, Accident 4.5.1.1.2, "line break occurs within vault due to earthquake."

It was postulated that a line break could occur within a ventilated vault because of a design basis earthquake. The vault would be located between the separations facility and the HLW vitrification facility. The pump pressure to the line would be 1,430 kPa (207 psi).

E.6.3.4.1 Scenario and Source-term Development for Seismic Induced Line Break in Vault

It was determined a maximum respirable spray release from the ruptured line with a pump pressure of 1,430 kPa (207 psi) would be approximately 7.6 L/min (2.0 gal/min) (Shire et al. 1995 and Jacobs 1996). The total released quantity would be drawn through a double-stage HEPA filter before being released to the environment.

Assumptions were as follows:

- The spray was limited to 16 hours (960 minutes); and
- HEPA filters provided an assumed LPF of 1.0E-05.

The source-term was calculated as follows:

(7.6 L/minutes) · (960 minutes) · (1.0E-05) = 7.3E-02 L (1.9E-02 gal).

E.6.3.4.2 Probability of Seismic Induced Line Break in Vault

The annual exceedance frequency of the event was assumed to be 6.5E-04 (Shire et al. 1995 and Jacobs 1996). This is the frequency of a 0.23 g design basis earthquake at the Hanford Site. It is assumed the leak would occur given the probability of the design basis earthquake. Based on 25 years of operation the probability was calculated to be 1.6E-02.

E.6.3.4.3 Radiological Consequences of Seismic Reduced Line Break in Vault

The radiological dose to the receptors from the previous source-term was calculated by the GENII computer code using the methodology discussed in Section E.1.1.4. The results (Shire et al. 1995 and Jacobs 1996) are summarized in Table E.6.3.12.

Table E.6.3.12 Dose Consequence for Seismic Reduced Line Break in Vault

E.6.3.4.4 Radiological Cancer Risk of Seismic Induced Line Break in Vault

Based on a dose-to-risk conversion factor of 4.0E-04 LCF per person-rem for the workers and noninvolved workers and 5.0E-04 per person-rem for the general public, the LCFs and the LCF risk (point estimate) were calculated for the receptors and presented in Table E.6.3.13. The calculations show there would be no LCFs attributable to this exposure if the accident occurs for the bounding or nominal scenarios.

Table E.6.3.13 Latent Cancer Fatality Risk from Seismic Induced Line Break in Vault

E.6.3.4.5 Chemical Consequences of Seismic Induced Line Break in Vault

The chemical exposure to the receptors from the postulated accident was calculated in Appendix A of the accident data package (Shire et al. 1995 and Jacobs 1996) and summarized in the exposure column in Tables E.6.3.14 and E.6.3.15 for the nominal and bounding toxic effects, respectively, and Tables E.6.3.16 and E.6.3.17 for the nominal and bounding corrosive/irritant effects, respectively. The tables compare the concentration of postulated chemical releases to acute exposure criteria (ERPGs) discussed in Section 1.1.7.

Table E.6.3.14 Comparison of Nominal Chemical Concentrations to Toxic Concentration Limits for Pretreatment Spray Release - SST Solids

Table E.6.3.15 Comparison of Bounding Chemical Concentrations to Toxic Concentration Limits for Pretreatment Spray Release - SST Solids

Table E.6.3.16 Comparison of Nominal Chemical Concentrations to Corrosive/Irritant Concentration Limits for Pretreatment Spray Release - SST Solids

Table E.6.3.17 Comparison of Bounding Chemical Concentrations to Corrosive/Irritant Concentration Limits for Pretreatment Spray Release - SST Solids

Toxic Impact from Chemical Exposure

Under nominal conditions (Table E.6.3.14), the cumulative acute hazard ratios for the MEI worker, MEI noninvolved worker, and MEI general public were less than 1.0, indicating that no adverse acute health effects would be expected for these three receptors. Under bounding conditions (Table E.6.3.15), the cumulative acute hazard ratios for the MEI worker, MEI noninvolved worker, and MEI general public were less than 1.0, indicating that no adverse acute health effects would be expected for these three receptors.

Corrosive/Irritant Impact from Chemical Exposure

Under nominal conditions (Table E.6.3.16), the cumulative acute hazard ratios for the MEI worker, MEI noninvolved worker, and MEI general public were less than 1.0, indicating that no adverse acute health effects would be expected for these three receptors. Under bounding conditions (Table E.6.3.17), the cumulative acute hazard ratios for the MEI worker, MEI noninvolved worker, and MEI general public were less than 1.0, indicating that no adverse acute health effects would be expected for these three receptors.

Under both nominal and bounding conditions, the probability of a pretreatment spray release is 1.63E-02.

E.6.3.5 Treatment Accidents

The treatment section of the Accident Screening Table (Table E.6.3.1) shows the radiological consequences to be insignificant for all credible accidents. The dominant accident was identified as Accident 4.5.4.4 "A Canister Dropped Due to Mechanical Failure or Human Error."

E.6.3.5.1 Source-term for Breached Canister

The source-term for a 24-hour release through a two-stage HEPA filter was calculated in Shire (Shire et al. 1995 and Jacobs 1996) to be 2.5E-06 grams (8.8E-08 ounces).

E.6.3.5.2 Radiological Consequences of Immobilization Accident

Accident 4.5.4.4, "a canister dropped due to mechanical failure or human error," has the highest dose consequences. As calculated in the accident data package (Shire et al. 1995 and Jacobs 1996) the radiological dose to the receptors are shown in Table E.6.3.18.

Table E.6.3.18 Dose Consequence for Breached Canister

E.6.3.5.3 Probability of Breached Canister

The annual frequency of the accident was considered in the accident data package (Shire et al. 1995 and Jacobs 1996) to be 6.0E-01. This was based on the frequency of a canister being dropped during transfer of 3.0E-04 per transfer and 2,000 transfers per year. Based on 25 years of operation the probability was calculated to be 1.0E+00.

E.6.3.5.4 Radiological Cancer Risk of Breached Canister

The LCFs and the LCF risk (point estimate) were calculated for the receptors and presented in Table E.6.3.19.

Table E.6.3.19 Latent Cancer Fatality Risk from Breached Canister

The calculations show there would be no LCFs attributable to this exposure for the bounding or nominal scenarios.

E.6.3.5.5 Chemical Consequences of Breached Canister

No chemical consequences were evaluated in (Shire et al. 1995 and Jacobs 1996) since the release would first pass through a two-stage HEPA filters that would reduce the source-term to a very small amount, well below the cumulative ratio of exposure to ERPG-1 values for toxic or corrosive/irritant chemicals.

E.6.3.6 Disposal/Storage Accidents

No design basis accidents resulting in a radiological or chemical consequences to the receptors were identified. This is largely due to the vitrified waste form of the material and the engineered structural packaging of the vitrified LAW in burial vaults and vitrified HLW in shipping containers.

E.6.3.7 Beyond Design Basis Accidents

The beyond design basis accident is a seismic event resulting in the collapse of a SST. In the event of a 0.43 g earthquake, a SST could potentially collapse (LANL 1995). This event is not dependent on the remediation alternative but has the same annual frequency regardless of the alternative that is chosen. The length of time unremediated waste would remain in tanks that have not been backfilled would vary depending on the alternative and would affect the probability of the event. The probability of the event is the product of the annual frequency of the earthquake and the number of years the waste remains untreated in the unstabilized tanks.

At smaller annual frequencies, larger earthquakes could occur resulting in greater destruction and larger numbers of LCF to the onsite and offsite populations. In addition to population exposures from the collapsed SSTs, the impact to other Hanford Site facilities and operations would potentially add to the chemical and radiological risk. This would be a severe earthquake that would cause catastrophic structural damage in the Tri-Cities and the Hanford Site with expected extensive loss of life. There would be injuries and fatalities resulting from collapsed buildings and homes, fires, and traffic accidents. However, this section evaluates the radiological and chemical impacts resulting from the collapse of one SST.

E.6.3.7.1 Source-Term Development

It was conservatively assumed that the radiological and chemical contaminants in the headspace are available for release. The collapse of a portion of the dome and overburden compresses the vapor in the headspace as it descends, enhancing the vapor release rate by a sudden pressure difference. Assuming for each tank a respirable concentration of contaminants in the headspace of 100 mg/m^3, a liquid SpG of 1.5, and a headspace volume of 1,000 m^3 (Shire et al. 1995 and Jacobs 1996), the potential source-term contribution from the headspace release was calculated as follows:

$$(100\ \text{mg/m}^3) \cdot (1\ \text{g}/1{,}000\ \text{mg}) \cdot (1\ \text{L}/1{,}000\ \text{g}) \cdot (1{,}000\ \text{m}^3) \cdot (1/1.5) = 6.67\text{E-}02\ \text{L}\ (1.8\text{E-}02\ \text{gal}).$$

It was conservatively assumed that the liquids had been pumped from the tanks so that the tanks contained only solids and the MAR was 2,500 L (660 gal) for each tank. It was postulated that the fall of the dome and overburden generated an air movement sufficient to suspend a fraction of the MAR. Assuming the respirable release fraction to be 2.0E-03 (Shire et al. 1995 and Jacobs 1996), the potential source-term contribution was calculated as follows:

$$(2{,}500\ \text{L}\ [660\ \text{gal}]) \cdot (2.0\text{E-}03) = 5.0\ \text{L}\ (1.3\ \text{gal}).$$

It was postulated that prevailing winds resuspend a respirable fraction of the MAR (2,500 L [660 gal]). A respirable release fraction of 4.0E-05/hr for 24 hours was assumed. The potential source-term contribution from resuspension was calculated as follows:

$$(2{,}500\ \text{L}\ [660\ \text{gal}]) \cdot (4.0\text{E-}05/\text{hr}) \cdot (24\ \text{hr}) = 2.4\ \text{L}\ (0.6\ \text{gal}).$$

The combined source-term for the acute release is calculated as follows:

$$(6.67\text{E-}02\ \text{L}) + (5.00\text{E+}00\ \text{L}) + (2.4\ \text{L}) = 7.4\ \text{L}\ (2.0\ \text{gal}).$$

E.6.3.7.2 Probability of a Beyond Design Basis Earthquake

This earthquake has a calculated annual exceedance frequency of approximately 1.40E-04 (WHC 1996b). The probability for this scenario based on 25 years of operation was therefore estimated to be 3.5E-03.

E.6.3.7.3 Radiological Consequences from a Beyond Design Basis Earthquake

The radiological dose to the receptors from the previous source-term was calculated by the GENII computer code (Napier et al. 1988) using the methodology previously discussed in Section E.1.1.6. The results are presented in Table E.6.3.20.

Table E.6.3.20 Dose Consequence from Seismic Event

E.6.3.7.4 Radiological Cancer Risk from a Beyond Design Basis Earthquake

The LCFs and LCF point estimate risk are presented in Table E.6.3.21.

Table E.6.3.21 Latent Cancer Fatality Risk from Seismic Event

In the bounding scenario, all 10 workers would potentially receive a fatal dose and assumably die directly after the exposure. There would also be 10 LCFs attributed to the exposure to the noninvolved workers and two LCFs to the general public if the accident occurred. The nominal scenario calculations show there would be no LCFs.

E.6.3.7.5 Chemical Consequences from a Beyond Design Basis Earthquake

Potential acute hazards associated with a beyond design basis earthquake are identical to those summarized in Tables E.2.2.16 (toxic chemicals, nominal conditions), E.2.2.17 (toxic chemicals, bounding conditions), E.2.2.18 (corrosive/irritant chemicals, nominal conditions) and E.2.2.19 (corrosive/irritant chemicals, bounding conditions) for the No Action alternative.

Under bounding conditions, chemical impacts were not evaluated for the MEI worker because all workers would receive a lethal radiation dose, as described previously.

Toxic Impact from Chemical Exposure

Under nominal conditions, the cumulative acute hazard ratio for the MEI worker was 2.64E+00 for ERPG-1, indicating that only mild transient effects would be expected. For the MEI noninvolved worker, the cumulative acute health hazard was 2.59E+00 for ERPG-3, indicating the potential for irreversible health effects that could be life threatening. This acute hazard ratio was primarily attributable to TOC (approximately 84 percent of the total hazard ratio). The TOC is assumed to be equivalent in toxicity to tributylphosphate, which is the most acutely toxic constituent of the organic analytes identified. Tributylphosphate was used as a surrogate because an inventory of the various chemicals that make up the TOC class is not available. The cumulative acute hazard ratio for the nearest noninvolved worker population consisting of 335 workers located 290 m (950 ft) away was less than 1.0 for all ERPGs, suggesting that no acute health effects would be expected.

Under bounding conditions (Table E.2.2.17), the cumulative hazard ratios for the MEI and nearest noninvolved worker population (335 workers located 290 m (950 ft) away) were 2.15E+03 and 7.80E+00 for ERPG-3, respectively. These ratios were primarily attributable to:

- Uranium (approximately 47 percent of the total hazard ratio);
- Oxalate (approximately 24 percent of the total hazard ratio); and
- Mercury (approximately 13 percent of the total hazard ratio).

This exceedance of the ERPG-3 criterion for the nearest noninvolved worker population would not be expected to result in irreversible health effects or place these workers in a life-threatening situation for the following reasons.

- ERPG-3 is defined as a concentration in which a receptor can be exposed for 1 hour without irreversible health effects. Because the Hanford Site has an in-place emergency response plan designed to evacuate workers within 1 hour of an accident, workers would be expected to evacuate their location and move to an area where potential exposures would be well below ERPG-3. Therefore, this worker population would not be exposed to airborne concentrations that would be either life threatening or result in irreversible health effects.

- The estimated air concentrations of chemicals as a result of this accident were based on very conservative meteorology, which results in movement of a plume directly toward the worker population at a relatively slow rate with minimal wind dispersion. If less conservative meteorological parameters were used, wind dispersion would cause the estimated air concentrations of chemicals to be substantially less, and the ERPG-3 criterion would not be exceeded.
- Only the bounding toxic chemical evaluation exceeded ERPG-3, while the nominal evaluation was well below 1.00E+00 for ERPG-3, suggesting that the noninvolved worker population would not receive an exposure that would result in any permanent health effects.

The cumulative acute hazard ratio for the next nearest noninvolved worker population, composed of 1,500 people and located 1,780 m (5,840 ft) away, was 2.15E+00 for ERPG-2, indicating that reversible acute health effects would be expected. The cumulative acute hazard ratio for the MEI general public was 1.76E+00 for ERPG-2, indicating that reversible acute health effects would be expected.

Corrosive/Irritant Impact from Chemical Exposure

Under nominal conditions (Table E.2.2.18), the cumulative acute hazard ratios for the MEI worker, MEI noninvolved worker and nearest noninvolved worker (335 workers at 290 m [950 ft]) were 2.47E+01, 5.10E+02 and 1.85E+00, respectively, for ERPG-3, indicating the potential for irreversible health effects that could be life threatening. These ratios were almost entirely attributable to sodium, which was assumed to be equivalent to sodium hydroxide in corrosive/irritant effects. As discussed previously, this exceedance of the ERPG-3 criterion would not be expected to result in irreversible or life threatening health effects. For the next nearest noninvolved worker population (1,500 workers at 1,780 m [5,840 ft]), the cumulative acute hazard ratio was 1.20E+00 for ERPG-1, indicating that only mild irreversible irritant effects would be anticipated. For the MEI general public, the cumulative acute hazard ratio was less than 1.0 for all ERPGs, and no acute health effects would be expected.

Under bounding conditions, the cumulative acute hazard ratios for the MEI noninvolved worker and nearest noninvolved worker (335 workers at 290 m [950 ft]) were 7.31E+02 and 2.65E+00, respectively, for ERPG-3, indicating the potential for irreversible health effects that could be life threatening. These acute hazard ratios were primarily attributable to:

- Sodium (approximately 83 percent of the total hazard ratio); and
- Calcium (approximately 10 percent of the total hazard ratio).

As discussed previously, this exceedance of the ERPG-3 criterion would not be expected to result in irreversible or life threatening health effects.

For the next nearest noninvolved worker and MEI general public, the cumulative acute hazard ratios were 1.74E+00 and 1.42E+00, respectively, for ERPG-1, indicating that only mild, transient irritant effects would be expected.

Under both nominal and bounding conditions, the probability of a seismic event is 3.50E-03.

E.6.3.8 Occupational Injuries and Fatalities

The number of operation personnel to support the Ex Situ Intermediate Separations alternative was estimated (Jacobs 1996) and is summarized as follows:

- Retrieval operations - 3.74E+04 person-years; and
- Vitrification operations - 1.73E+04 person-years.

The total recordable injuries and illnesses, lost workday cases, and fatalities were calculated as follows:

Total Recordable Cases = (5.47E+04 person-years) · (2.2E+00 incidences/100 person-years) = 1.20E+03

Lost Workday Cases = (5.47E+04 person-years) · (1.1E+00 incidences/100 person-years) = 6.02E+02

Fatalities = (5.47E+04 person-years) · 3.2E-03 fatalities/100 person-years) = 1.75E+00

E.6.4 POST-REMEDIATION ACCIDENT

E.6.4.1 Deflagration in Storage Tank

After 99 percent of the tank waste has been removed from each tank, the probability of a tank generating enough hydrogen to exceed the LFL is considered to be incredible.

E.6.4.2 Seismic-Induced Rupture of Stabilized Tanks

As discussed in Section E.4.4.2, displacement on a fault that would increase exposure to the waste after remediation is considered incredible. The tanks would most likely crack, allowing increased infiltration to the groundwater.

E.6.5 SUMMARY OF ACCIDENTS

The potential consequences from nonradiological and nonchemical accidents that include occupational and transportation impacts are summarized in Table E.6.5.1. The LCFs associated with representative accidents for each component of the alternative are summarized in Table E.6.5.2 along with the probability of the accident. The chemical hazards associated with representative accidents for each component of the alternative are summarized in Table E.6.5.3. The chemical hazard is expressed as an exceedance of the ERPG threshold values.

Table E.6.5.1 Summary of Potential Nonradiological/Nonchemical Accident Consequences

Table E.6.5.2 Summary of Potential Radiological Accident Consequences

Table E.6.5.3 Chemical Exposures Resulting from Potential Operations and Transportation Accidents

E.7.0 EX SITU NO SEPARATIONS ALTERNATIVE

The Ex Situ No Separations alternative would not separate waste into LAW and HLW streams. The SST and DST waste would be blended and vitrified (as HLW) into glass cullet. The cullet would be packed into canisters, placed into concrete overpack shielding casks, and held on interim site storage pads to await shipment to a permanent potential geologic repository for final disposal. This section analyzes and compares the construction, operation, and transportation risks associated with this alternative.

E.7.1 CONSTRUCTION ACCIDENTS

The construction activities associated with the Ex Situ No Separations alternative are discussed in Appendix B of the EIS. It should be noted there are no radiological or chemical consequences associated with construction accidents. Occupational injuries, illnesses, and fatalities resulting from potential construction accidents are calculated in the following text.

The number of construction personnel to support the Ex Situ No Separations alternative was estimated (Jacobs 1996) and summarized as follows:

- Waste transfer system upgrade - 1.63E+02 person-years;
- Retrieval construction - 1.06E+04 person-years;
- Vitrification construction - 1.48E+04 person-years; and
- Grout fill MUSTs and closure - 4.62E+02 person-years.

The total recordable injuries and illnesses, lost workday cases, and fatalities were calculated as follows:

Total Recordable Cases = (2.60E+04 person-years) · (9.75E+00 incidences/100 person-years) = 2.54E+03.

Lost Workday Cases = (2.60E+04 person-years) · (2.45E+00 incidences/100 person-years) = 6.38E+02.

Fatalities = (2.60E+04 person-years) · (3.20E-03 fatalities/100 person-years) = 8.33E-01.

E.7.2 TRANSPORTATION ACCIDENTS

Transportation activities associated with this alternative are:

- Transporting residual SST waste and MUST waste to vitrification facility;
- Transporting earthen material from onsite borrow site to fill tank voids;
- Transporting earthen material from onsite borrow site for Hanford Barrier;
- Transporting construction material to the Hanford Site; and
- Employees commuting to work each day.

E.7.2.1 Radiological Consequences

The methodology for determining radiological consequences from accidents while transporting residual SST waste and MUST waste to a vitrification facility was previously discussed in Section E.6.2.1.

The receptor dose and LCF risk resulting from the accident analysis for retrieval of MUST waste and SST residuals is presented in Table E.7.2.1 for the integrated population and Table E.7.2.2 for the MEI worker and MEI general public. There would be no LCFs resulting from an accident while transporting retrieved waste onsite.

Table E.7.2.1 Integrated Radiological Impact from Retrieval Transport Accidents

Table E.7.2.2 MEI Radiological Impact from Retrieval Transport Accidents

E.7.2.2 Chemical Consequences

The chemical exposure for the Ex Situ No Separations alternative is the same as that previously discussed in Section 6.2.2 for the Ex Situ Intermediate Separations alternative with the exclusion of the dicyclopentadiene. The results are reproduced in Table E.7.2.3. The general public's exposure to anhydrous ammonia would exceed the ratio of exposure to ERPG-3 by 1.24E+01 for corrosive/irritant chemicals. Consequently, this exposure to the MEI general public could result in potential lethal effects.

Table E.7.2.3 Comparison of Chemical Concentrations to Corrosive/Irritant Concentration Limits for the Ex Situ No Separations Alternative

E.7.2.3 Occupational Injuries and Fatalities

Truck and Rail Transportation

Injuries and fatalities resulting from direct impact of transportation accidents are analyzed in this subsection. Rail and truck transportation activities to transport materials and supplies to the site for this alternative were estimated in the No Separations data package (WHC 1995c) and summarized in Table E.7.2.4.

Table E.7.2.4 Summary of Transportation Activities for the Ex Situ No Separations Alternative

The number of injuries and fatalities were calculated by multiplying the total distance traveled in each zone shown in Table E.7.2.5 by the appropriate unit risk factors shown in Table E.1.3.1. The distance traveled in the population zones were calculated using the methodology previously discussed in Section E.1.3.

Table E.7.2.5 Distance Traveled in Population Zones for the Ex Situ No Separations Alternative

The expected injuries and fatalities resulting from transportation accidents associated with the Ex Situ No Separations alternative are summarized in Table E.7.2.6.

Table E.7.2.6 Injuries and Fatalities Resulting from Truck and Rail Transportation Accidents for the Ex Situ No Separations Alternative

Employee Traffic

In addition to transporting materials and supplies to and from the Hanford Site by truck and rail, site workers and other personnel required to perform the various activities would be driving to the site in their vehicles. The total person-years to perform the activities was estimated at 6.73E+04 (Jacobs 1996). Each person was assumed to work 260 days of the year. The round-trip distance traveled to work from the Tri-Cities area was estimated at 140 km (87 mi) with an estimated 1.35 passengers per vehicle (DOE 1994a). The total employee vehicle distance was therefore calculated as follows:

$$(6.73\text{E+}04 \text{ person-years}) \cdot (260 \text{ days/year}) \cdot (140 \text{ km/day}) \cdot (1/1.35) = 1.82\text{E+}09 \text{ km } (1.1\text{E+}09 \text{ mi})$$

To calculate the expected number of injuries and fatalities resulting from vehicle accidents, the injury/fatality rates discussed in Section E.1.3 were used. The expected number of injuries and fatalities resulting from employee vehicle accidents were calculated as follows:

Injuries = (1.82E+09 km) · (7.1E-07 injuries/km) = 1.30E+03

Fatalities = (1.82E+09 km) · (8.98E-09 fatalities/km) = 1.63E+01

Cumulative Transportation Injuries and Fatalities

The cumulative, nonradiological and nontoxicological injuries and fatalities incurred as a direct result of traffic accident impacts is the sum of the truck and rail transport and employee vehicle accidents. The results are summarized in Table E.7.2.7.

Table E.7.2.7 Cumulative Injuries and Fatalities from Traffic Impacts for the Ex Situ No Separations Alternative

E.7.3 OPERATION ACCIDENTS

The radiological and chemical operation accidents, consequences, and risk for the Ex Situ No Separations alternative are summarized in the following text.

E.7.3.1 Continued Operation - Mispositioned Jumper Accident - Tank Waste Transfers

The dominant continued operations accident during tank waste transfer is the mispositioned jumper accident previously discussed in the No Action alternative in Section E.2.2.1 and summarized as follows:

Source-term - The source-term resulting from a spray release in Section E.2.2.1.1 was calculated to be 52 L (14 gal).

Probability - The frequency of a mispositioned jumper in Section E.2.2.1.2 was 1.1E-02 per year. The Ex Situ No Separations continued operation activity was based on 22.5 years of operations; therefore, the probability was calculated to be 2.5E-01.

Radiological Consequences - The radiological consequences presented in Table E.2.2.2 are reproduced in Table E.7.3.1.

Table E.7.3.1 Dose Consequence from Mispositioned Jumper

Radiological Cancer Risk - The LCFs calculated in Section E.2.2.1.4 are the same for the Ex Situ No Separations alternative; however, the LCF risk (point estimate) is not the same due to the difference in probabilities. The LCFs and the LCF risk are calculated in Table E.7.3.2. The bounding scenario calculations show all 10 workers potentially receive a fatal dose and assumably die directly after the exposure if the accident occurred. There would be approximately seven LCFs from the noninvolved worker population and two from the general public. The nominal scenario calculations show there would be no LCFs.

Table E.7.3.2 Latent Cancer Fatality Risk from Mispositioned Jumper

Chemical Consequences

Potential acute hazards associated with a mispositioned jumper are identical to those summarized in Tables E.2.2.4 (toxic chemicals, nominal conditions), E.2.2.5 (toxic chemicals, bounding conditions), E.2.2.6 (corrosive/irritant chemicals, nominal conditions) and E.2.2.7 (corrosive/irritant chemicals, bounding conditions) for the No Action alternative.

Toxic Impact from Chemical Exposure

Under nominal conditions (Table E.2.2.4), the cumulative acute hazard ratios for the MEI worker, MEI noninvolved worker, and MEI general public were less than 1.0, indicating that no adverse acute health effects would be expected for these three receptors. Under bounding conditions (Table E.2.2.5), the MEI worker was not evaluated because death would occur from exposure to radionuclides. The cumulative acute hazard ratio for the MEI noninvolved worker was 5.36E+00 for ERPG-2, indicating that reversible acute health effects would be expected. This acute hazard ratio was primarily attributable to mercury (approximately 89 percent of the overall hazard ratio). No adverse acute health effects were predicted for the MEI general public under bounding conditions.

Corrosive/Irritant Impact from Chemical Exposure

Under nominal conditions (Table E.2.2.6), the cumulative acute hazard ratio for the MEI worker was 2.70E+00 for ERPG-3, indicating the potential for irreversible health effects that could be life threatening. This acute hazard ratio was almost entirely attributable to sodium assumed to be equivalent to sodium hydroxide in corrosive/irritant effects. For the MEI noninvolved worker, the cumulative acute hazard ratio for ERPG-1 was 3.00E+00, indicating that only mild, reversible irritant effects would be expected. No acute health impacts were predicted for the MEI general public under nominal conditions. Under bounding conditions (Table E.2.2.7), the MEI worker was not evaluated because death would occur from exposure to radionuclides. For the MEI noninvolved worker, the cumulative acute hazard ratio for ERPG-1 was 4.36E+00, indicating that only mild reversible irritant effects would be expected. No acute health impacts were predicted for the MEI general public under bounding conditions.

Under both nominal and bounding conditions, the probability of a mispositioned jumper is 2.48E-01.

E.7.3.2 Continued Operations Accident -Waste Storage Tanks

The dominant accident is a hydrogen deflagration in a waste storage tank previously discussed in the No Action alternative in Section E.2.2.2.1 and summarized as follows:

Source-term - The source-term resulting from the fire in Section E.2.2.2.1 was calculated to be 2.4 L (0.6 gal).

Probability - The frequency of the hydrogen deflagration in a waste storage tank in Section E.2.2.2.2 was estimated to be 7.2E-03 per year. The Ex Situ No Separations alternative was based on 23 years of operation, therefore the probability was calculated to be 1.7E-01.

Radiological Consequences - The radiological consequences presented in Table E.2.2.8 are reproduced in Table E.7.3.3.

Table E.7.3.3 Dose Consequence from Hydrogen Deflagration in Waste Storage Tank

Radiological Cancer Risk - The LCFs calculated in Section E.2.2.2.4 are the same for the Ex Situ No Separations alternative. However, the LCF point estimate risk is not the same due to the difference in probabilities. The LCF and the LCF risk are calculated in Table E.7.3.4.

Table E.7.3.4 Latent Cancer Fatality Risk from Hydrogen Deflagration in Waste Storage Tank

In the bounding scenario all 10 workers would potentially receive a fatal dose and assumably die directly after the exposure. There would also be 10 LCFs attributed to the exposure to the noninvolved workers and 2 LCFs to the general public if the accident occurred. The noninvolved scenario calculations show there would be no LCFs.

Chemical Consequences

Potential acute hazards associated with a hydrogen burn in a waste storage tank are identical to those summarized in Tables E.2.2.10 (toxic chemicals, nominal conditions), E.2.2.11 (toxic chemicals, bounding conditions), E.2.2.12 (corrosive/irritant chemicals, nominal conditions) and E.2.2.13 (corrosive/irritant chemicals, bounding conditions) for the No Action alternative.

Under bounding conditions, chemical impacts were not evaluated for the MEI worker because all workers would receive a lethal radiation dose, as discussed previously.

Toxic Impact from Chemical Exposure

Under nominal conditions (Table E.2.2.10), the cumulative acute hazard ratio for the MEI worker was 1.57E+00 for ERPG-2, indicating that reversible acute health effects would be expected. This acute hazard ratio was primarily attributable to TOC (approximately 87 percent of the overall ERPG-2 ratio). The TOC is assumed to be equivalent in toxicity to tributylphosphate, which is the most acutely toxic constituent of the organic analytes identified. Tributylphosphate was used as a surrogate because an inventory of the various chemicals that make up the TOC class is not available. For the MEI noninvolved worker, the cumulative acute hazard ratio for ERPG-3 was 9.38E+00, indicating the potential for irreversible health effects that could be life threatening. This acute hazard ratio was also primarily attributable to TOC (approximately 90 percent of the overall ERPG-3 ratio) However, the MEI noninvolved worker is a hypothetical worker assumed to be located 100m (330 ft) from the source area. The nearest noninvolved worker population is located 290 m (950 ft) from the source area and had no cumulative acute hazard ratios greater than 1.0 for any of the ERPGs, indicating that no acute health effects would be expected for the nearest noninvolved worker population. Likewise, no acute health effects were predicted for the MEI general public under nominal conditions.

Under bounding conditions (Table E.2.2.11), the cumulative acute hazard ratio for the MEI noninvolved worker was 4.54E+02 for ERPG-3, indicating the potential for irreversible health effects that could be life-threatening. This acute hazard ratio is primarily attributable to:

- Oxalate (approximately 37 percent of the total hazard ratio);
- Beryllium (approximately 13 percent of the total hazard ratio);
- Cadmium (approximately 14 percent of the total hazard ratio);
- Uranium (approximately 12 percent of the total hazard ratio); and
- TOC (approximately 8 percent of the total hazard ratio).

As discussed previously, this is a hypothetical receptor located 100m (330 ft) from the source. The cumulative acute hazard ratio for the nearest noninvolved worker population located 290 m (950 ft) from the source was 1.65E+00 for ERPG-3, indicating the potential for irreversible health effects that could be life-threatening for 335 workers. This hazard ratio was attributable to the same toxic chemicals listed above. This exceedance of the ERPG-3 criterion for the nearest noninvolved worker population would not be expected to result in irreversible health effects or place these workers in a life-threatening situation for the following reasons.

- ERPG-3 is defined as a concentration in which a receptor can be exposed for 1 hour without irreversible health effects. Because the Hanford Site has an in-place emergency response plan designed to evacuate workers within 1 hour of an accident, workers would be expected to evacuate their location and move to an area where potential exposures would be well below ERPG-3. Therefore, this worker population would not be exposed to airborne concentrations that would be either life threatening or result in irreversible health effects;
- The estimated air concentrations of chemicals as a result of this accident were based on very conservative meteorology, which results in movement of a plume directly toward the worker population at a relatively slow rate with minimal wind dispersion. If less conservative meteorological parameters were used, wind dispersion would cause the estimated air concentrations of chemicals to be substantially less, and the ERPG-3 criterion would not be exceeded; and
- Only the bounding toxic chemical evaluation exceeded ERPG-3, while the nominal evaluation was well below 1.00E+00 for ERPG-3, suggesting that the noninvolved worker population would not receive an exposure that would result in any permanent health effects.

The next nearest noninvolved worker population is located 1,780 m (5,840 ft) from the source and contains 1,500 workers. The cumulative acute hazard ratio was less than 1.0 for all ERPGs, indicating that no acute health effects would be expected for this population of workers. No acute health impacts were predicted for the MEI general public.

Corrosive/Irritant Impact from Chemical Exposure

Under nominal conditions (Table E.2.2.12), the cumulative acute hazard ratio for the MEI worker was 3.82E+00 for ERPG-3, indicating the potential for irreversible corrosive/irritant effects that could be life threatening. For the MEI noninvolved worker, the cumulative acute hazard ratio for ERPG-3 was 7.89E+01 and would indicate irreversible corrosive/irritant effects that could be life threatening for this hypothetical receptor. This hazard ratio was primarily attributable to sodium which was assumed to be equivalent to sodium hydroxide in corrosive/irritant effects. For the nearest noninvolved worker population (290 m [950 ft]) composed of 335 workers, the cumulative acute hazard ratio for ERPG-1 was 1.38E+01, indicating that only mild reversible effects would be expected. No acute health impacts were predicted for the MEI general public under nominal conditions.

Under bounding conditions (Table E.2.2.13), the cumulative acute hazard ratio for the MEI noninvolved worker was 1.91E+02 for ERPG-3, indicating irreversible health effects that could be life threatening for this hypothetical receptor. This hazard ratio was primarily attributable to:

- Sodium as sodium hydroxide (approximately 75 percent of the total hazard ratio);
- Chromium (approximately 14 percent of the total hazard ratio); and
- Calcium (approximately 6 percent of the total hazard ratio).

For the nearest noninvolved worker population (290 m [950 ft]) composed of 335 workers, the cumulative acute hazard ratio was 1.74 for ERPG-2, indicating that reversible acute effects would be expected. No acute health impacts were predicted for the MEI general public under nominal conditions.

Under both nominal and bounding conditions, the probability of a hydrogen deflagration event in a waste storage tank is 1.66E-01.

E.7.3.3 Retrieval - Loss of Filtration Accident

The dominant retrieval operations accident is the loss of filtration accident previously discussed in the Ex Situ Intermediate Separations alternative in Section E.6.3.3 and is summarized as follows:

Source-term - The source-term resulting from the airborne release in Section E.6.3.3.1 was calculated to be 2.5E-01L (6.6E-02 gal).

Probability - The frequency of a loss of filtration in Section E.6.3.3.2 was 8.8E-06 per year. The Ex Situ No Separations retrieval activity was based on 23 years of operations; therefore, the probability was calculated to be 2.2E-04.

Radiological Consequences - The radiological consequences presented in Section 6.3.3.3 are reproduced in Table E.7.3.5.

Table E.7.3.5 Dose Consequence from Loss of Filtration

Radiological Cancer Risk - The LCFs and the LCF point estimate risk were calculated for the receptors and are presented in Table E.7.3.6.

Table E.7.3.6 Latent Cancer Fatality Risk from Loss of Filtration

In the bounding scenario all 10 workers would potentially receive a fatal dose and assumably die directly after the exposure. The calculations show there would be less than one LCF attributed to the exposure to the noninvolved workers and the general public if the accident occurred. The nominal scenario calculations show there would be no LCFs.

Chemical Consequences

The chemical exposure to the receptors from the postulated accident was calculated in Appendix A of the accident data package (Shire et al. 1995 and Jacobs 1996) and summarized in the exposure column in Tables E.6.3.8 and E.6.3.9 for the nominal and bounding toxic effects, respectively, and Tables E.6.3.10 and E.6.3.11 for the nominal and bounding corrosive/irritant effects, respectively. The tables compare the concentration of postulated chemical releases to acute exposure criteria (ERPGs) discussed in Section 1.1.7.

Under bounding conditions, chemical impacts were not evaluated for the MEI worker because all workers would receive a lethal radiation dose, as discussed previously.

Toxic Impact from Chemical Exposure

Under nominal conditions (Table E.6.3.8), the cumulative acute hazard ratio for the MEI worker was less than 1.0 for all ERPGs, indicating that no adverse acute health effects would be expected. For the MEI noninvolved worker, the cumulative acute hazard ratio was 1.84E+00 for ERPG-1, indicating that only mild, transient acute health effects would be expected. No acute health effects were predicted for the MEI general public under nominal conditions.

Under bounding conditions (Table E.6.3.9), the cumulative acute hazard ratio for the MEI noninvolved worker was 7.27E+01 for ERPG-3, indicating the potential for irreversible health effects that could be life-threatening. This acute hazard ratio is primarily attributable to:

- Uranium (approximately 48 percent of the total hazard ratio);
- Oxalate (approximately 24 percent of the total hazard ratio);
- Mercury (approximately 13 percent of the total hazard ratio); and
- TOC (approximately 7 percent of the total hazard ratio).

As discussed previously, this is a hypothetical receptor located 100m (330 ft) from the source. The cumulative acute hazard ratio for the nearest noninvolved worker population (335 workers) located 290 m (950 ft) from the source was 5.40E+00 for ERPG-2, indicating that reversible acute health effects would be expected. No acute health impacts were predicted for the MEI general public.

Corrosive/Irritant Impact from Loss of Filtration

Under nominal conditions (Table E.6.3.10), the cumulative acute hazard ratio for the MEI worker was 2.11E+00 for ERPG-2, indicating that reversible corrosive/irritant effects would be expected. For the MEI noninvolved worker, the cumulative acute hazard ratio for ERPG-3 was 1.72E+01 and would indicate irreversible corrosive/irritant effects that could be life threatening for this hypothetical receptor. This hazard ratio was primarily attributable to sodium which was assumed to be equivalent to sodium hydroxide in corrosive/irritant effects. For the nearest noninvolved worker population (290 m [950 ft]) composed of 335 workers, the cumulative acute hazard ratio for ERPG-1 was 3.02E+00, indicating that only mild, transient irritant effects would be expected. No acute health impacts were predicted for the MEI general public under nominal conditions.

Under bounding conditions (Table E.6.3.11), the cumulative acute hazard ratio for the MEI noninvolved worker was 2.47E+01 for ERPG-3, indicating irreversible health effects that could be life threatening for this hypothetical receptor. This hazard ratio was primarily attributable to :

- Sodium as sodium hydroxide (approximately 82 percent of the total hazard ratio);and
- Calcium (approximately 9 percent of the total hazard ratio).

For the nearest noninvolved worker population (290 m [950 ft]) composed of 335 workers, the cumulative acute hazard ratio was 4.38 for ERPG-1, indicating that only mild, transient irritant effects would be expected. No acute health impacts were predicted for the MEI general public under nominal conditions.

Under both nominal and bounding conditions, the probability of a loss of filtration event is 2.02E-04.

E.7.3.4 Treatment - Canister of Vitrified High-Level Waste Inadvertently Drops and Ruptures

The dominant immobilization operations accident is the "canister of vitrified HLW inadvertently drops and ruptures" accident previously discussed in the Ex Situ Intermediate Separations alternative in Section E.6.3.5 and summarized as follows:

Source-term - The source-term resulting from the airborne release in Section E.6.3.5.1 was calculated to be 2.5E-06 g (8.8E-08 oz) based on a solid glass form in the canister. The canisters for the Ex Situ No Separations alternative are filled with glass cullet, therefore it was assumed that the MAR would be increased by a factor of two. This increase would result in a source-term of 5.0E-06 g (1.8E-07 oz).

Probability - The frequency of the accident in Section E.6.3.5.2 was 6.0E-01 per year. The Ex Situ No Separation treatment activity was based on 23 years of operations; therefore, the probability was calculated to be 1.0E+00.

Radiological Consequences - The radiological consequences in Section 6.3.5.3 were increased by a factor of two, based on the increased inventory, and are presented in Table E.7.3.7.

Table E.7.3.7 Dose Consequence from Breached Canister

Radiological Cancer Risk - The LCFs and the LCF point estimate risk were calculated for the receptors and are presented in Table E.7.3.8. The calculations show that there would be no LCFs attributable to this exposure if the accident occurs for the bounding or nominal scenarios.

Table E.7.3.8 Latent Cancer Fatality Risk from Breached Canister

Chemical Consequences - No chemical consequences were evaluated (Shire et al. 1995 and Jacobs 1996) since the release would first pass through two-stage HEPA filters that would reduce the source-term to a very small amount, well below the cumulative ratio of exposure to ERPG-1 values for toxic or corrosive/irritant chemicals.

E.7.3.5 Beyond Design Basis Accidents

The beyond design basis accident is a seismic event resulting in the collapse of a SST. In the event of a 0.43 g earthquake, a SST could potentially collapse (LANL 1995). This event is not dependent on the remediation alternative but has the same annual frequency regardless of the alternative that is chosen. The length of time unremediated waste would remain in tanks that have not been backfilled would vary depending on the alternative and would affect the probability of the event. The probability of the event is the product of the annual frequency of the earthquake and the number of years the waste remains untreated in the unstabilized tanks.

At smaller annual frequencies, larger earthquakes could occur resulting in greater destruction and larger numbers of LCF to the onsite and offsite populations. In addition to population exposures from the collapsed SSTs, the impact to other Hanford Site facilities and operations would potentially add to the chemical and radiological risk. This would be a severe earthquake that would cause catastrophic structural damage in the Tri-Cities and the Hanford Site with expected extensive loss of life. There would be injuries and fatalities resulting from collapsed buildings and homes, fires, and traffic accidents. However, this section evaluates the radiological and chemical impacts resulting from the collapse of one SST.

E.7.3.5.1 Source-Term Development

It was conservatively assumed that the radiological and chemical contaminants in the headspace are available for release. The collapse of a portion of the dome and overburden compresses the vapor in the headspace as it descends, enhancing the vapor release rate by a sudden pressure difference. Assuming for each tank a respirable concentration of contaminants in the headspace of 100 mg/m^3, a liquid SpG of 1.5, and a headspace volume of 1,000 m^3 (Shire et al. 1995 and Jacobs 1996), the potential source-term contribution from the headspace release was calculated as follows:

$$(100\ \text{mg/m}^3) \cdot (1\ \text{g}/1{,}000\ \text{mg}) \cdot (1\ \text{L}/1{,}000\ \text{g}) \cdot (1{,}000\ \text{m}^3) \cdot (1/1.5) = 6.67\text{E-}02\ \text{L}\ (1.8\text{E-}02\ \text{gal}).$$

It was conservatively assumed that the liquids had been pumped from the tanks so that the tanks contained only solids and the MAR was 2,500 L (660 gal) for each tank. It was postulated that the fall of the dome and overburden generated an air movement sufficient to suspend a fraction the MAR. Assuming the respirable release fraction to be 2.0E-03 (Shire et al. 1995 and Jacobs 1996), the potential source-term contribution was calculated as follows:

$$(2{,}500 \text{ L } [660 \text{ gal}]) \cdot (2.0\text{E-}03) = 5.0 \text{ L } (1.3 \text{ gal}).$$

It was postulated that prevailing winds resuspend a respirable fraction of the MAR (2,500 L [660 gal]). A respirable release fraction of 4.0E-05/hr for 24 hours was assumed. The potential source-term contribution from resuspension was calculated as follows:

$$(2{,}500 \text{ L } [660 \text{ gal}]) \cdot (4.0\text{E-}05/\text{hr}) \cdot (24 \text{ hr}) = 2.4 \text{ L } (0.6 \text{ gal}).$$

The combined source-term for the acute release is calculated as follows:

$$(6.67\text{E-}02 \text{ L}) + (5.00\text{E+}00 \text{ L}) + (2.4 \text{ L}) = 7.4 \text{ L } (2.0 \text{ gal}).$$

E.7.3.5.2 Probability of a Beyond Design Basis Earthquake

This earthquake has a calculated annual exceedance frequency of approximately 1.40E-04 (WHC 1996b). The probability for this scenario based on 23 years of operation was therefore estimated to be 3.2E-03.

E.7.3.5.3 Radiological Consequences from a Beyond Design Basis Earthquake

The radiological dose to the receptors from the previous source-term was calculated by the GENII computer code (Napier et al. 1988) using the methodology previously discussed in Section E.1.1.6. The results are presented in Table E.7.3.9.

Table E.7.3.9 Dose Consequence from Seismic Event

E.7.3.5.4 Radiological Cancer Risk from a Beyond Design Basis Earthquake

The LCFs and LCF point estimate risk are presented in Table E.7.3.10.

Table E.7.3.10 Latent Cancer Fatality Risk from Seismic Event

In the bounding scenario, all 10 workers would potentially receive a fatal dose and assumably die directly after the exposure. There would also be 10 LCFs attributed to the exposure to the noninvolved workers and two LCFs to the general public if the accident occurred. The nominal scenario calculations show there would be no LCFs.

E.7.3.5.5 Chemical Consequences from a Beyond Design Basis Earthquake

Potential acute hazards associated with a beyond design basis earthquake are identical to those summarized in Tables E.2.2.16 (toxic chemicals, nominal conditions), E.2.2.17 (toxic chemicals, bounding conditions), E.2.2.18 (corrosive/irritant chemicals, nominal conditions) and E.2.2.19 (corrosive/irritant chemicals, bounding conditions) for the No Action alternative.

Under bounding conditions, chemical impacts were not evaluated for the MEI worker because all workers would receive a lethal radiation dose, as described previously.

Toxic Impact from Chemical Exposure

Under nominal conditions, the cumulative acute hazard ratio for the MEI worker was 2.64E+00 for ERPG-1, indicating that only mild transient effects would be expected. For the MEI noninvolved worker, the cumulative acute health hazard was 2.59E+00 for ERPG-3, indicating the potential for irreversible health effects that could be life threatening. This acute hazard ratio was primarily attributable to TOC (approximately 84 percent of the total hazard ratio). The TOC is assumed to be equivalent in toxicity to tributylphosphate, which is the most acutely toxic constituent of the organic analytes identified. Tributylphosphate was used as a surrogate because an inventory of the various chemicals that make up the TOC class is not available. The cumulative acute hazard ratio for the nearest noninvolved worker population (consisting of 335 workers located 290 m [950 ft] away) was less than 1.0 for all ERPGs, suggesting that no acute health effects would be expected.

Under bounding conditions (Table E.2.2.17), the cumulative hazard ratios for the MEI and nearest noninvolved worker (335 workers located 290 m [950 ft] away) were 2.15E+03 and 7.80E+00 for ERPG-3, respectively. These ratios were primarily attributable to:

- Uranium (approximately 47 percent of the total hazard ratio);
- Oxalate (approximately 24 percent of the total hazard ratio); and
- Mercury (approximately 13 percent of the total hazard ratio).

This exceedance of the ERPG-3 criterion for the nearest noninvolved worker population would not be expected to result in irreversible health effects or place these workers in a life-threatening situation for the following reasons.

- ERPG-3 is defined as a concentration in which a receptor can be exposed for 1 hour without irreversible health effects. Because the Hanford Site has an in-place emergency response plan designed to evacuate workers within 1 hour of an accident, workers would be expected to evacuate their location and move to an area where potential exposures would be well below ERPG-3. Therefore, this worker population would not be exposed to airborne concentrations that would be either life threatening or result in irreversible health effects;
- The estimated air concentrations of chemicals as a result of this accident were based on very conservative meteorology, which results in movement of a plume directly toward the worker population at a relatively slow rate with minimal wind dispersion. If less conservative meteorological parameters were used, wind dispersion would cause the estimated air concentrations of chemicals to be substantially less, and the ERPG-3 criterion would not be exceeded; and
- Only the bounding toxic chemical evaluation exceeded ERPG-3, while the nominal evaluation was well below 1.00E+00 for ERPG-3, suggesting that the noninvolved worker population would not receive an exposure that would result in any permanent health effects.

Corrosive/Irritant Impact from Chemical Exposure

Under nominal conditions (Table E.2.2.18), the cumulative acute hazard ratios for the MEI worker, MEI noninvolved worker and nearest noninvolved worker (335 workers at 290 m [950 ft]) were 2.47E+01, 5.10E+02 and 1.85E+00, respectively, for ERPG-3, indicating the potential for irreversible health effects that could be life threatening. These ratios were almost entirely attributable to sodium, which was assumed to be equivalent to sodium hydroxide in corrosive/irritant effects. As discussed previously, this exceedance of the ERPG-3 criterion would not be expected to result in irreversible or life threatening health effects. For the next nearest noninvolved worker population (1,500 workers at 1,780 m [5,840 ft]), the cumulative acute hazard ratio was 1.20E+00 for ERPG-1, indicating that only mild irreversible irritant effects would be anticipated. For the MEI general public, the cumulative acute hazard ratio was less than 1.0 for all ERPGs and no acute health effects would be expected.

Under bounding conditions, the cumulative acute hazard ratios for the MEI noninvolved worker and nearest noninvolved worker (335 workers at 290 m [950 ft]) were 7.31E+02 and 2.65E+00, respectively, for ERPG-3, indicating the potential for irreversible health effects that could be life threatening. These acute hazard ratios were primarily attributable to:

- Sodium (approximately 83 percent of the total hazard ratio); and
- Calcium (approximately 10 percent of the total hazard ratio).

As discussed previously, this exceedance of the ERPG-3 criterion would not be expected to result in irreversible or life threatening health effects.

For the next nearest noninvolved worker and MEI general public, the cumulative acute hazard ratios were 1.74E+00 and 1.42E+00, respectively, for ERPG-1, indicating that only mild, transient irritant effects would be expected.

Under both nominal and bounding conditions, the probability of a seismic event is 3.22E-03.

E.7.3.6 Occupation Injuries, Illnesses, and Fatalities from Operations

The number of operation personnel to support the Ex Situ No Separations alternative was estimated (Jacobs 1996) and is summarized as follows:

- Retrieval operations - 3.15E+04 person-years.
- Vitrification operations - 9.78E+03 person-years.

The total recordable injuries and illnesses, lost workday cases, and fatalities were calculated as follows:

Total Recordable Cases = (4.13E+04 person-years) · (2.2E+00 incidences/100 person-years) = 9.08E+02

Lost Workday Cases = (4.13E+04 person-years) · (1.1E+00 incidences/100 person-years) = 4.54+02

Fatalities = (4.13E+04 person-years) · (3.20E-03 fatalities/100 person-years) = 1.32E+00

E.7.4 CALCINATION SUBALTERNATIVE

A subalternative to vitrification for the No Separations alternative is calcination. Rather than vitrifying the waste stream, it would be calcined. There would be no change in the construction and operation accidents.

E.7.4.1 Transportation

Transportation activities associated with this alternative are:

- Transporting residual SST waste and MUSTs waste to calcination facility;
- Transporting earthen material from borrow sites to fill tank voids and for Hanford Barrier;
- Transporting construction material to Hanford Site; and
- Employees commuting to work each day.

E.7.4.1.1 Radiological Consequences

The methodology for determining radiological consequences from accidents while transporting residual SST waste and MUST waste to a calcination facility was previously discussed in Section E.6.2.1.

The receptor dose and LCF risk resulting from the accident analysis for retrieval of MUST waste and SST residuals is presented in Table E.7.4.1 for the integrated population and Table E.7.4.2 for the MEI worker and MEI general public.

Table E.7.4.1 Integrated Radiological Impact from Retrieval Transport Accidents

Table E.7.4.2 MEI Radiological Impact from Retrieval Transport Accidents

The number of injuries and fatalities were calculated by multiplying the total distance traveled in each zone shown in Table E.7.4.4 by the appropriate unit risk factors shown in Table E.1.3.1. The distance traveled in the population zones were calculated using the methodology previously discussed in Section E.1.3.

There would be no LCFs resulting from an accident while transporting retrieved waste onsite.

E.7.4.1.2 Chemical Exposure

The chemical exposure for calcination would be the same as that previously discussed for vitrification in Section

E.7.2.2. The general public exposure to anhydrous ammonia would exceed the ratio of exposure to ERPG-3 by 1.24E+01 for corrosive/irritant chemicals and could potentially result in lethal effects.

E.7.4.1.3 Occupational Injuries and Fatalities

Truck and Rail Transportation

Injuries and fatalities resulting from direct impact of transportation accidents are analyzed in this subsection. Rail and truck transportation activities to transport materials and supplies to the site for this alternative were estimated in the No Separations data package (WHC 1995c) and summarized in Table E.7.4.3.

Table E.7.4.3 Summary of Transportation Activities for the Ex Situ No Separations Alternative (Calcination)

Table E.7.4.4 Distance Traveled in Population Zones for the Calcination Subalternative

The expected injuries and fatalities resulting from transportation accidents associated with the Ex Situ No Separations alternative are summarized in Table E.7.4.5.

Table E.7.4.5 Injuries and Fatalities Resulting from Truck and Rail Transportation Accidents for the Calcination Subalternative

Employee Traffic

Employee Traffic would be the same as for Vitrification, as calculated in Section E.7.2.2, which would result in 1.30E+03 injuries and 1.63E+01 fatalities.

The number of injuries and fatalities were calculated by multiplying the total distance traveled in each zone shown in Table E.7.4.4 by the appropriate unit risk factors shown in Table E.1.3.1. The distance traveled in the population zones were calculated using the methodology previously discussed in Section E.1.3.

The expected injuries and fatalities resulting from transportation accidents associated with the calcination subalternative are summarized in Table E.7.4.5.

Cumulative Transportation Injuries and Fatalities

The cumulative nonradiological and nontoxicological injuries and fatalities incurred as a direct result of traffic accident impacts are the sum of the truck and rail transport and employee vehicle accidents. The employee impacts from calcination would remain the same as vitrification. The results are summarized in Table E.7.4.6.

Table E.7.4.6 Cumulative Injuries and Fatalities from Traffic Impacts for the Calcination Subalternative

E.7.5 POST-REMEDIATION ACCIDENT

E.7.5.1 Deflagration in Storage Tank

After 99 percent of the tank waste has been removed from each tank, the probability of a tank generating enough hydrogen to exceed the LFL is considered to be incredible.

E.7.5.2 Seismic Induced Rupture of Stabilized Tanks

As discussed in Section E.4.4.2, displacement on a fault that would increase exposure to the waste after remediation is considered to be incredible. The tanks would most likely crack, allowing increased infiltration to the groundwater.

For the MEI general public, the cumulative ratio of exposure to ERPG-1 values for toxic chemicals was 4.06E-02, which does not exceed the ratio of 1.0 and indicates no acute effects.

Corrosive/Irritant Impact from Chemical Exposure

For the MEI noninvolved worker located 100m (330 ft) from the accident, the cumulative ratio of exposure to ERPG-3 values for corrosive/irritant chemicals was 9.08E+00 and exceeds 1.0, which indicates potential irreversible health effects or death. This acute hazard index is primarily attributable to:

- Sodium hydroxide (approximately 62 percent of the total hazard);
- Chromium (approximately 14 percent of the total hazard); and
- Calcium (approximately 13 percent of the total hazard).

For the noninvolved worker population located 290 m (950 ft) from the accident, the cumulative ratio of exposure to ERPG-1 values for corrosive/irritant chemicals was 1.66E+00, which exceeds the ratio of 1.0 and indicates only minor, transient effects. For the noninvolved worker population located 1,780 m (5,840 ft) from the accident, the cumulative ratio of exposure to ERPG-1 values was 2.23E-02, which does not exceed the ratio of 1.0 and indicates no acute effects.

For the MEI general public, the cumulative ratio of exposure to ERPG-1 values for corrosive/irritant chemicals was 1.82E-02, which does not exceed the ratio of 1.0 and indicates no acute effects.

E.7.6 SUMMARY OF ACCIDENTS

The potential consequences from nonradiological and nonchemical accidents that include occupational and transportation impacts are summarized in Table E.7.6.1 for vitrification and Table E.7.6.2 for calcination. The LCFs associated with representative accidents for each component of the alternative for both vitrification and calcination are summarized in Table E.7.6.3 along with the probability of the accident. The chemical hazards associated with representative accidents for each component of the alternative for both vitrification and calcination are summarized in Table E.7.6.4. The chemical hazard is expressed as an exceedance of the ERPG threshold values.

Table E.7.6.1 Summary of Potential Nonradiological/Nonchemical Accident Consequences - Vitrification

Table E.7.6.2 Summary of Potential Nonradiological/Nonchemical Accident Consequences - Calcination

Table E.7.6.3 Summary of Potential Radiological Accident Consequences - Vitrification and Calcination

Table E.7.6.4 Chemical Exposures Resulting from Potential Operations and Transportation Accidents

E.8.0 EX SITU EXTENSIVE SEPARATIONS ALTERNATIVE

The Ex Situ Extensive Separations alternative would separate waste into LAW and HLW streams. This alternative is very similar to the Ex Situ Intermediate Separations alternative. This section analyzes and compares the construction, and transportation risks associated with this alternative.

E.8.1 CONSTRUCTION ACCIDENTS

The construction activities associated with the Ex Situ Extensive Separations alternative are discussed in Appendix B of the EIS. It should be noted that there are no radiological or chemical consequences associated with construction accidents. Occupational injuries, illnesses, and fatalities resulting from potential construction accidents are calculated in the following text.

The number of construction personnel to support the Ex Situ Extensive Separations alternative was estimated at an average 3.71E+04 person-years (Jacobs 1996).

The total recordable injuries and illnesses, lost workday cases, and fatalities were calculated as follows:

Total Recordable Cases = (3.71E +04 person-years) · (9.75E+00 incidences/100 person-years) = 3.61E+03

Lost Workday Cases = (3.71E +04 person-years) · (2.45E+00 incidences/100 person-years) = 9.08E+02

Fatalities = (3.71E +04 person-years) · (3.20E-03 fatalities/100 person-years) = 1.19E+00

E.8.2 TRANSPORTATION ACCIDENTS

Transportation activities associated with this alternative are:

- Transport construction material to the site;
- Transporting residual SST waste and MUST waste to vitrification facility;
- Transporting earthen material from onsite borrow site to fill tank voids;
- Transporting earthen material from onsite borrow site for Hanford Barrier; and
- Employees commuting to work each day.

E.8.2.1 Radiological Consequences

The methodology for determining radiological consequences from accidents while transporting residual SST waste and MUST waste to a vitrification facility was previously discussed in Section E.6.2.1.

The receptor dose and LCF risk resulting from the accident analysis for retrieval of MUST waste and SST residuals are presented in Table E.8.2.1 for the integrated population and Table E.8.2.2 for the MEI worker and MEI general public.

Table E.8.2.1 Integrated Radiological Impact from Retrieval Transport Accidents

Table E.8.2.2 Maximally-Exposed Individual Radiological Impact from Retrieval Transport Accidents

There would be no LCFs resulting from an accident while transporting retrieved waste onsite.

E.8.2.2 Chemical Exposure

There would be no change from the Ex Situ Intermediate Separations alternative discussed in Section 6.2.2. The general public exposure to anhydrous ammonia would exceed the ratio of exposure to ERPG-3 by 1.24E+01 and sodium hydroxide would exceed the ratio of exposure to ERPG-1 by 2.45E+00 for corrosive/irritant chemicals. Based on the magnitude of the exceedance for anhydrous ammonia, this exposure could potentially result in lethal effects.

E.8.2.3 Occupational Injuries and Fatalities

Truck and Rail Transportation

Injuries and fatalities resulting from direct impact of transportation accidents are analyzed in this subsection. Rail and truck transportation activities to transport materials and supplies to the site for this alternative were estimated in the Extensive Separations engineering data package (WHC 1995e) and summarized in Table E.8.2. 3 .

Table E.8.2.3 Summary of Transportation Activities for the Ex Situ Extensive Separations Alternative

The number of injuries and fatalities were calculated by multiplying the total distance traveled in each zone shown in Table E.8.2. 4 by the appropriate unit risk factors shown in Table E.1.3.1. The distance traveled in the population zones were calculated using the methodology previously discussed in Section E.1.3.

Table E.8.2.4 Distance Traveled in Population Zones for the Ex Situ Extensive Separations Alternative

The expected injuries and fatalities resulting from transportation accidents associated with the Ex Situ Extensive Separations alternative are summarized in Table E.8.2. 5 .

Table E.8.2.5 Injuries and Fatalities Resulting from Truck and Rail Transportation Accidents for the Ex Situ Extensive Separations Alternative

Employee Traffic

In addition to transporting materials and supplies to and from the Hanford Site by truck and rail, site workers and other personnel required to perform the various activities would be driving to work in their vehicles. The total person-years to perform the activities was estimated at 8.14E+04 (Jacobs 1996). Each person was assumed to work 260 days of the year. The round-trip distance traveled to work from the Tri-Cities area was estimated at 140 km (87 mi) with an estimated 1.35 passengers per vehicle (DOE 1994a). The total employee vehicle distance was therefore calculated as follows:

(8.14E +04 person-years) · (260 days/year) · (140 km/day) · (1/1.35) = 2.20E+09 km

To calculate the expected number of injuries and fatalities resulting from vehicle accidents, the injury/fatality rates discussed in Section E.1.3 were used. The expected number of injuries and fatalities resulting from employee vehicle accidents were calculated as follows:

Injuries = (2.20E+09 km) · (7.1E-07 injuries/km) = 1.57E+03

Fatalities = (2.20E+09 km) · (8.98E-09 fatalities/km) = 1.97E+01

Cumulative Transportation Injuries and Fatalities

The cumulative nonradiological and nontoxicological injuries and fatalities incurred as a direct result of traffic accident impacts are the sum of the truck and rail transport and employee vehicle accidents. The results are summarized in Table E.8.2. 6 .

Table E.8.2.6 Cumulative Fatalities and Injuries from Traffic Impacts for the Ex Situ Extensive Separations Alternative

E.8.3 OPERATION ACCIDENTS

The radiological and chemical operation accidents, consequences, and risk for the Ex Situ Extensive Separations alternative are analyzed in the following subsections.

E.8.3.1 Continued Operation Accident - Tank Waste Transfers

The dominant continued operations accident during tank waste transfer is the mispositioned jumper accident previously discussed in the No Action alternative in Section E.2.2.1 and summarized as follows:

Source-Term - The source-term resulting from a spray release in Section E.2.2.1.1 was calculated to be 52 L (14 gal).

Probability - The frequency of a mispositioned jumper in Section E.2.2.1.2 was 1.1E-02 per year. The Ex Situ Extensive Separations continued operation accident was based on 26 years of operations; therefore, the probability was calculated to be 2.9E-01.

Radiological Consequences - The radiological consequences presented in Table E.2.2.2 are reproduced in Table E.8.3.1.

Table E.8.3.1 Dose Consequence from Mispositioned Jumper

Radiological Cancer Risk - The LCFs calculated in Section E.2.2.1.4 are the same for the Ex Situ Extensive Separations alternative; however, the LCF point estimate risk is not the same due to the difference in probabilities. The LCFs and the LCF risk are calculated in Table E.8.3.2. The bounding scenario calculations show all 10 workers would potentially receive a fatal dose and assumably die directly after the exposure if the accident occurred. There would be approximately seven LCFs in the noninvolved worker population and two LCFs in the general public. The nominal scenario calculations show there would be no LCFs.

Table E.8.3.2 Latent Cancer Fatality Risk from Mispositioned Jumper

Chemical Consequences

Potential acute hazards associated with a mispositioned jumper are identical to those summarized in Tables E.2.2.4 (toxic chemicals, nominal conditions), E.2.2.5 (toxic chemicals, bounding conditions), E.2.2.6 (corrosive/irritant chemicals, nominal conditions) and E.2.2.7 (corrosive/irritant chemicals, bounding conditions) for the No Action alternative.

Toxic Impact from Chemical Exposure

Under nominal conditions (Table E.2.2.4), the cumulative acute hazard ratios for the MEI worker, MEI noninvolved worker, and MEI general public were less than 1.0, indicating that no adverse acute health effects would be expected for these three receptors. Under bounding conditions (Table E.2.2.5), the MEI worker was not evaluated because death would occur from exposure to radionuclides. The cumulative acute hazard ratio for the MEI noninvolved worker was 5.36E+00 for ERPG-2, indicating that reversible acute health effects would be expected. This acute hazard ratio was primarily attributable to mercury (approximately 89 percent of the overall hazard ratio). No adverse acute health effects were predicted for the MEI general public under bounding conditions.

Corrosive/Irritant Impact from Chemical Exposure

Under nominal conditions (Table E.2.2.6), the cumulative acute hazard ratio for the MEI worker was 2.70E+00 for ERPG-3, indicating the potential for irreversible health effects that could be life threatening. This acute hazard ratio was almost entirely attributable to sodium assumed to be equivalent to sodium hydroxide in corrosive/irritant effects. For the MEI noninvolved worker, the cumulative acute hazard ratio for ERPG-1 was 3.00E+00, indicating that only mild reversible irritant effects would be expected. No acute health impacts were predicted for the MEI general public under nominal conditions. Under bounding conditions (Table E.2.2.7), the MEI worker was not evaluated because death would occur from exposure to radionuclides. For the MEI noninvolved worker, the cumulative acute hazard ratio for ERPG-1 was 4.36E+00, indicating that only mild reversible irritant effects would be expected. No acute health impacts were predicted for the MEI general public under bounding conditions.

Under both nominal and bounding conditions, the probability of a mispositioned jumper is 2.86E-01.

E.8.3.2 Continued Operations Accident - Waste Storage Tanks

The dominant accident is a hydrogen deflagration in a waste storage tank previously discussed in the No Action alternative in Section E.2.2.2.1 and is summarized as follows:

Source-Term - The source-term resulting from the fire in Section E.2.2.2.1 was calculated to be 2.4 L (0.6 gal).

Probability - The frequency of the hydrogen deflagration in a waste storage tank in Section E.2.2.2 was estimated to be 7.2E-03 per year. The probability of the scenario based on 26 years of operation was therefore estimated to be 1.9E-01.

Radiological Consequences - The radiological consequences presented in Table E.2.2.8 are reproduced in Table E.8.3.3.

Table E.8.3.3 Dose Consequence from Hydrogen Deflagration in Waste Storage Tank

Radiological Cancer Risk - The LCFs calculated in Section E.2.2.2.4 are the same for the Ex Situ Extensive Separations alternative. However, the LCF risk (point estimate) is not the same due to the difference in probabilities. The LCF and LCF risk are calculated in Table E.8.3.4.

Table E.8.3.4 Latent Cancer Fatality Risk from Hydrogen Deflagration in Waste Storage Tank

In the bounding scenario all 10 workers would potentially receive a fatal dose and assumably die directly after the exposure. There would be 10 LCFs attributed to the exposure to the noninvolved workers and 2 LCFs to the general public if the accident occurred. The nominal scenario calculations show there would be no LCFs.

Chemical Consequences

Potential acute hazards associated with a hydrogen burn in a waste storage tank are identical to those summarized in Tables E.2.2.10 (toxic chemicals, nominal conditions), E.2.2.11 (toxic chemicals, bounding conditions), E.2.2.12 (corrosive/irritant chemicals, nominal conditions) and E.2.2.13 (corrosive/irritant chemicals, bounding conditions) for the No Action alternative.

Under bounding conditions, chemical impacts were not evaluated for the MEI worker because all workers would receive a lethal radiation dose, as discussed previously.

Toxic Impacts for Chemical Exposure

Under nominal conditions (Table E.2.2.10), the cumulative acute hazard ratio for the MEI worker was 1.57E+00 for ERPG-2, indicating that reversible acute health effects would be expected. This acute hazard ratio was primarily attributable to TOC (approximately 87 percent of the overall ERPG-2 ratio). The TOC is assumed to be equivalent in toxicity to tributylphosphate, which is the most acutely toxic constituent of the organic analytes identified. Tributylphosphate was used as a surrogate because an inventory of the various chemicals that make up the TOC class is not available. For the MEI noninvolved worker, the cumulative acute hazard ratio for ERPG-3 was 9.38E+00, indicating the potential for irreversible health effects that could be life threatening. This acute hazard ratio was also primarily attributable to TOC (approximately 90 percent of the overall ERPG-3 ratio). However, the MEI noninvolved worker is a hypothetical worker assumed to be located 100 m (330 ft) from the source area. The nearest noninvolved worker population is located 290 m (950 ft) from the source area and had no cumulative acute hazard ratios greater than 1.0 for any of the ERPGs, indicating that no acute health effects would be expected for the nearest noninvolved worker population. Likewise, no acute health effects were predicted for the MEI general public under nominal conditions.

Under bounding conditions (Table E.2.2.11), the cumulative acute hazard ratio for the MEI noninvolved worker was 4.54E+02 for ERPG-3, indicating the potential for irreversible health effects that could be life-threatening. This acute hazard ratio is primarily attributable to:

- Oxalate (approximately 37 percent of the total hazard ratio);
- Beryllium (approximately 13 percent of the total hazard ratio);
- Cadmium (approximately 14 percent of the total hazard ratio);
- Uranium (approximately 12 percent of the total hazard ratio); and
- TOC (approximately 8 percent of the total hazard ratio).

As discussed previously, this is a hypothetical receptor located 100 m (330 ft) from the source. The cumulative acute hazard ratio for the nearest noninvolved worker population located 290 m (950 ft) from the source was 1.65E+00 for ERPG-3, indicating the potential for irreversible health effects that could be life threatening for 335 workers. This hazard ratio was attributable to the same toxic chemicals listed above. This exceedance of the ERPG-3 criterion for the nearest noninvolved worker population would not be expected to result in irreversible health effects or place these workers in a life-threatening situation for the following reasons.

- ERPG-3 is defined as a concentration in which a receptor can be exposed for 1 hour without irreversible health effects. Because the Hanford Site has an in-place emergency response plan designed to evacuate workers within 1 hour of an accident, workers would be expected to evacuate their location and move to an area where potential exposures would be well below ERPG-3. Therefore, this worker population would not be exposed to airborne concentrations that would be either life threatening or result in irreversible health effects.
- The estimated air concentrations of chemicals as a result of this accident were based on very conservative meteorology, which results in movement of a plume directly toward the worker population at a relatively slow rate with minimal wind dispersion. If less conservative meteorological parameters were used, wind dispersion would cause the estimated air concentrations of chemicals to be substantially less, and the ERPG-3 criterion would not be exceeded.
- Only the bounding toxic chemical evaluation exceeded ERPG-3, while the nominal evaluation was well below 1.00E+00 for ERPG-3, suggesting that the noninvolved worker population would not receive an exposure that would result in any permanent health effects.

The next nearest noninvolved worker population is located 1,780 m (5,840 ft) from the source and contains 1,500 workers. The cumulative acute hazard ratio was less than 1.0 for all ERPGs, indicating that no acute health effects would be expected for this population of workers. No acute health impacts were predicted for the MEI general public.

Corrosive/Irritant Impact from Chemical Exposure

Under nominal conditions (Table E.2.2.12), the cumulative acute hazard ratio for the MEI worker was 3.82E+00 for ERPG-3, indicating the potential for irreversible corrosive/irritant effects that could be life threatening. For the MEI noninvolved worker, the cumulative acute hazard ratio for ERPG-3 was 7.89E+01 and would indicate irreversible corrosive/irritant effects that could be life threatening for this hypothetical receptor. This hazard ratio was primarily attributable to sodium, which was assumed to be equivalent to sodium hydroxide in corrosive/irritant effects. For the nearest noninvolved worker population (290 m [950 ft]) composed of 335 workers, the cumulative acute hazard ratio for ERPG-1 was 1.38E+01, indicating that only mild, reversible effects would be expected. No acute health impacts were predicted for the MEI general public under nominal conditions.

Under bounding conditions (Table E.2.2.13), the cumulative acute hazard ratio for the MEI noninvolved worker was 1.91E+02 for ERPG-3, indicating irreversible health effects that could be life threatening for this hypothetical receptor. This hazard ratio was primarily attributable to:

- Sodium as sodium hydroxide (approximately 75 percent of the total hazard ratio);

- Chromium (approximately 14 percent of the total hazard ratio); and
- Calcium (approximately 6 percent of the total hazard ratio).

For the nearest noninvolved worker population (290 m [950 ft]) composed of 335 workers, the cumulative acute hazard ratio was 1.74E+00 for ERPG-2, indicating that reversible acute effects would be expected. No acute health impacts were predicted for the MEI general public under nominal conditions.

Under both nominal and bounding conditions, the probability of a hydrogen deflagration event in a waste storage tank is 1.87E-01.

E.8.3. 3 Retrieval Accidents

The dominant retrieval operations accident is the loss of filtration accident previously discussed in the Ex Situ Intermediate Separations alternative in Section E.6.3. 3 and is summarized as follows:

Source-Term - The source-term resulting from the airborne release in Section E.6.3. 3 .1 was calculated to be 2.5E-01 L (6.6E-02 gal).

Probability - The frequency of a loss of filtration in Section E.6.3. 3 .2 was 8.8E-06 per year. The Ex Situ Extensive Separations retrieval activity was based on 26 years of operations; therefore, the probability was calculated to be 2.3E-04.

Radiological Consequences - The radiological consequences presented in Section 6.3. 3 .3 are reproduced in Table E.8.3. 5 .

Table E.8.3.5 Dose Consequence from Loss of Filtration

Radiological Cancer Risk - The LCFs and the LCF point estimate risk were calculated for the receptors and presented in Table E.8.3.6 .

Table E.8.3.6 Latent Cancer Fatality Risk from Loss of Filtration

In the bounding scenario all 10 workers would potentially receive a fatal dose and assumably die directly after the exposure. T he calculations show there would be less than one LCF attributed to the exposure to the noninvolved workers and the general public if the accident occurred. The nominal scenario calculations show there would be no LCFs.

Chemical Consequences

The chemical exposure to the receptors from the postulated accident was calculated in Appendix A of the accident data package (Shire et al. 1995 and Jacobs 1996) and summarized in the exposure column in Tables E.6.3.8 and E.6.3.9 for the nominal and bounding toxic effects, respectively, and Tables E.6.3.10 and E.6.3.11 for the nominal and bounding corrosive/irritant effects, respectively. The tables compare the concentration of postulated chemical releases to acute exposure criteria (ERPGs) discussed in Section 1.1.7.

Under bounding conditions, chemical impacts were not evaluated for the MEI worker because all workers would receive a lethal radiation dose, as discussed previously.

Toxic Impact from Chemical Exposure

Under nominal conditions (Table E.6.3.8), the cumulative acute hazard ratio for the MEI worker was less than 1.0 for all ERPGs, indicating that no adverse acute health effects would be expected. For the MEI noninvolved worker, the cumulative acute hazard ratio was 1.84E+00 for ERPG-1, indicating that only mild, transient acute health effects would be expected. No acute health effects were predicted for the MEI general public under nominal conditions.

Under bounding conditions (Table E.6.3.9), the cumulative acute hazard ratio for the MEI noninvolved worker was 7.27E+01 for ERPG-3, indicating the potential for irreversible health effects that could be life-threatening. This acute hazard ratio is primarily attributable to:

- Uranium (approximately 48 percent of the total hazard ratio);
- Oxalate (approximately 24 percent of the total hazard ratio);
- Mercury (approximately 13 percent of the total hazard ratio); and
- TOC (approximately 7 percent of the total hazard ratio).

As discussed previously, this is a hypothetical receptor located 100 m (330 ft) from the source. The cumulative acute hazard ratio for the nearest noninvolved worker population (335 workers) located 290 m (950 ft) from the source was 5.40E+00 for ERPG-2, indicating that reversible acute health effects would be expected. No acute health impacts were predicted for the MEI general public.

Corrosive/Irritant Impact from Loss of Filtration

Under nominal conditions (Table E.6.3.10), the cumulative acute hazard ratio for the MEI worker was 2.11E+00 for ERPG-2, indicating that reversible corrosive/irritant effects would be expected. For the MEI noninvolved worker, the cumulative acute hazard ratio for ERPG-3 was 1.72E+01 and would indicate irreversible corrosive/irritant effects that could be life threatening for this hypothetical receptor. This hazard ratio was primarily attributable to sodium, which was assumed to be equivalent to sodium hydroxide in corrosive/irritant effects. For the nearest noninvolved worker population (290 m [950 ft]) composed of 335 workers, the cumulative acute hazard ratio for ERPG-1 was 3.02E+00, indicating that only mild, transient irritant effects would be expected. No acute health impacts were predicted for the MEI general public under nominal conditions.

Under bounding conditions (Table E.6.3.11), the cumulative acute hazard ratio for the MEI noninvolved worker was 2.47E+01 for ERPG-3, indicating irreversible health effects that could be life threatening for this hypothetical receptor. This hazard ratio was primarily attributable to:

- Sodium as sodium hydroxide (approximately 82 percent of the total hazard ratio); and
- Calcium (approximately 9 percent of the total hazard ratio).

For the nearest noninvolved worker population (290 m [950 ft]) composed of 335 workers, the cumulative acute hazard ratio was 4.38E+00 for ERPG-1, indicating that only mild, transient irritant effects would be expected. No acute health impacts were predicted for the MEI general public under nominal conditions.

Under both nominal and bounding conditions, the probability of a loss of filtration event is 2.29E-04.

E.8.3. 4 Pretreatment Accidents

The dominant pretreatment operations accident is the seismic induced line break in vault accident previously discussed in the Ex Situ Intermediate Separations alternative in Section E.6.3. 4 and is summarized as follows:

Source-Term - The source-term resulting from the airborne release in Section E.6.3. 4 .1 was calculated to be 7.3E-02 L (1.9E-02 gal).

Probability - The annual exceedance frequency of the seismic event in Section E.6.3. 4 .2 was 6.5 E-05 per year. The Ex Situ Extensive Separations alternative was based on 2 6 years of operations, therefore, the probability was calculated to be 1.7E-02.

Radiological Consequences - The radiological consequences presented in Section 6.3. 4 .3 are reproduced in Table E.8.3. 7 .

Table E.8.3.7 Dose Consequence from Seismic Induced Line Break in Vault

Radiological Cancer Risk - The LCFs and the LCF point estimate risk were calculated for the receptors and presented in Table E.8.3.8 . The calculations show there would be no LCFs attributable to this exposure if the accident occurs for the bounding and nominal scenarios .

Table E.8.3.8 Latent Cancer Fatality Risk from Seismic Induced Line Break in Vault

Chemical Consequences

The chemical exposure to the receptors from the postulated accident was calculated in Appendix A of the accident data package (Shire et al. 1995 and Jacobs 1996) and summarized in the exposure column in Tables E.6.3.14 and E.6.3.15 for the nominal and bounding toxic effects, respectively, and Tables E.6.3.16 and E.6.3.17 for the nominal and bounding corrosive/irritant effects, respectively. The tables compare the concentration of postulated chemical releases to acute exposure criteria (ERPGs) discussed in Section 1.1.7.

Toxic Impact from Chemical Exposure

Under nominal conditions (Table E.6.3.14), the cumulative acute hazard ratios for the MEI worker, MEI noninvolved worker, and MEI general public were less than 1.0, indicating that no adverse acute health effects would be expected for these three receptors. Under bounding conditions (Table E.6.3.15), the cumulative acute hazard ratios for the MEI worker, MEI noninvolved worker, and MEI general public were less than 1.0, indicating that no adverse acute health effects would be expected for these three receptors.

Corrosive/Irritant Impact from Chemical Exposure

Under nominal conditions (Table E.6.3.16), the cumulative acute hazard ratios for the MEI worker, MEI noninvolved worker, and MEI general public were less than 1.0, indicating that no adverse acute health effects would be expected for these three receptors. Under bounding conditions (Table E.6.3.17), the cumulative acute hazard ratios for the MEI worker, MEI noninvolved worker, and MEI general public were less than 1.0, indicating that no adverse acute health effects would be expected for these three receptors.

Under both nominal and bounding conditions, the probability of a pretreatment spray release is 1.69E-02.

E.8.3. 5 Treatment Accidents

The dominant treatment operations accident is the "canister of vitrified HLW inadvertently drops and ruptures" accident previously discussed in the Ex Situ Intermediate Separations alternative in Section E.6.3.5 and is summarized as follows:

Source-Term - The source-term resulting from the airborne release in Section E.6.3. 5 .1 was calculated to be 2.5E-06 g (8.8E-08 oz).

Probability - The frequency of the accident in Section E.6.3. 5 .2 was 6.0E-01 per year. The Ex Situ Extensive Separations alternative was based on 2 6 years of operations; therefore, the probability was calculated to be 1.0E+00.

Radiological Consequences - The radiological consequences presented in Section 6.3. 5 .3 are reproduced in Table E.8.3. 9 .

Table E.8.3.9 Dose Consequence from Breached Canister

Radiological Cancer Risk - The LCFs and the LCF point estimate risk were calculated for the receptors and presented in Table E.8.3.10 . The calculations show there would be no LCFs attributable to this exposure if the accident occurs.

Table E.8.3.10 Latent Cancer Fatality Risk from Breached Canister

Chemical Consequences - No chemical consequences were evaluated (Shire et al. 1995 and Jacobs 1996) since the release would pass through two-stage HEPA filters that would reduce the source-term to a very small amount, well below the cumulative ratio of exposure to ERPG-1 values for toxic or corrosive/irritant chemicals.

E.8.3.6 Beyond Design Basis Accidents

The beyond design basis accident is a seismic event resulting in the collapse of a SST. In the event of a 0.43 g earthquake, a SST could potentially collapse (LANL 1995). This event is not dependent on the remediation alternative but has the same annual frequency regardless of the alternative that is chosen. The length of time unremediated waste would remain in tanks that have not been backfilled would vary depending on the alternative and would affect the probability of the event. The probability of the event is the product of the annual frequency of the earthquake and the number of years the waste remains untreated in the unstabilized tanks.

At smaller annual frequencies, larger earthquakes could occur resulting in greater destruction and larger numbers of LCF to the onsite and offsite populations. In addition to population exposures from the collapsed SSTs, the impact to other Hanford Site facilities and operations would potentially add to the chemical and radiological risk. This would be a severe earthquake that would cause catastrophic structural damage in the Tri-Cities and the Hanford Site with expected extensive loss of life. There would be injuries and fatalities resulting from collapsed buildings and homes, fires, and traffic accidents. However, this section evaluates the radiological and chemical impacts resulting from the collapse of one SST.

E.8.3.6.1 Source-Term Development

It was conservatively assumed that the radiological and chemical contaminants in the headspace are available for release. The collapse of a portion of the dome and overburden compresses the vapor in the headspace as it descends, enhancing the vapor release rate by a sudden pressure difference.

Assuming for each tank a respirable concentration of contaminants in the headspace of 100 mg/m^3, a liquid SpG of 1.5, and a headspace volume of 1,000 m^3 (Shire et al. 1995 and Jacobs 1996), the potential source-term contribution from the headspace release was calculated as follows:

$$(100\ \text{mg/m}^3) \cdot (1\ \text{g}/1{,}000\ \text{mg}) \cdot (1\ \text{L}/1{,}000\ \text{g}) \cdot (1{,}000\ \text{m}^3) \cdot (1/1.5) = 6.67\text{E-02 L } (1.8\text{E-02 gal}).$$

It was conservatively assumed that the liquids had been pumped from the tanks so that the tanks contained only solids and the MAR was 2,500 L (660 gal) for each tank. It was postulated that the fall of the dome and overburden generated an air movement sufficient to suspend a fraction the MAR. Assuming the respirable release fraction to be 2.0E-03 (Shire et al. 1995 and Jacobs 1996), the potential source-term contribution was calculated as follows:

$$(2{,}500\ \text{L}) \cdot (2.0\text{E-03}) = 5\ \text{L } (1.3\ \text{gal}) .$$

It was postulated that prevailing winds resuspend a respirable fraction of the MAR (2,500 L [660 gal]). A respirable release fraction of 4.0E-05/hr for 24 hours was assumed. The potential source-term contribution from resuspension was calculated as follows:

$$(2{,}500\ \text{L}) \cdot (4.0\text{E-05/hr}) \cdot (24\ \text{hr}) = 2.4\ \text{L } (0.6\text{E-01 gal}).$$

The combined source-term for the acute release is calculated as follows:

$$(6.67\text{E-02 L}) + (5.0\ \text{L}) + (2.4\ \text{L}) = 7.4\ \text{L } (2.0\ \text{gal}).$$

E.8.3.6.2 Probability of a Beyond Design Basis Earthquake

This earthquake has a calculated annual exceedance frequency of approximately 1.40E-04 (WHC 1996b). The probability for this scenario based on 26 years of operation was therefore estimated to be 3.6E-3.

E.8.3.6.3 Radiological Consequences from a Beyond Design Basis Earthquake

The radiological dose to the receptors from the previous source-term was calculated by the GENII computer code (Napier et al. 1988) using the methodology previously discussed in Section E.1.1.6. The results are presented in Table E.8.3.11.

Table E.8.3.11 Dose Consequence from Seismic Event

E.8.3.6.4 Radiological Cancer Risk from a Beyond Design Basis Earthquake

The LCFs and LCF point estimate risk are presented in Table E.8.3.12.

Table E.8.3.12 Latent Cancer Fatality Risk from Seismic Event

In the bounding scenario, all 10 workers would potentially receive a fatal dose and assumably die directly after the exposure. There would also be 10 LCFs attributed to the exposure to the noninvolved workers and two LCFs to the general public if the accident occurred. The nominal scenario calculations show there would be no LCFs.

E.8.3.6.5 Chemical Consequences from a Beyond Design Basis Earthquake

Potential acute hazards associated with a beyond design basis earthquake are identical to those summarized in Tables E.2.2.16 (toxic chemicals, nominal conditions), E.2.2.17 (toxic chemicals, bounding conditions), E.2.2.18 (corrosive/irritant chemicals, nominal conditions) and E.2.2.19 (corrosive/irritant chemicals, bounding conditions) for the No Action alternative.

Under bounding conditions, chemical impacts were not evaluated for the MEI worker because all workers would receive a lethal radiation dose, as described previously.

Toxic Impact from Chemical Exposure

Under nominal conditions, the cumulative acute hazard ratio for the MEI worker was 2.64E+00 for ERPG-1, indicating that only mild transient effects would be expected. For the MEI noninvolved worker, the cumulative acute health hazard was 2.59E+00 for ERPG-3, indicating the potential for irreversible health effects that could be life threatening. This acute hazard ratio was primarily attributable to TOC (approximately 84 percent of the total hazard ratio). The TOC is assumed to be equivalent in toxicity to tributylphosphate, which is the most acutely toxic constituent of the organic analytes identified. Tributylphosphate was used as a surrogate because an inventory of the various chemicals that make up the TOC class is not available. The cumulative acute hazard ratio, for the nearest noninvolved worker population consisting of 335 workers located 290 m (950 ft) away, was less than 1.0 for all ERPGs, suggesting that no acute health effects would be expected.

Under bounding conditions (Table E.2.2.17), the cumulative hazard ratios for the MEI and nearest noninvolved worker (335 workers located 290 m [950 ft] away) were 2.15E+03 and 7.80E+01 for ERPG-3, respectively. These ratios were primarily attributable to:

- Uranium (approximately 47 percent of the total hazard ratio);
- Oxalate (approximately 24 percent of the total hazard ratio); and
- Mercury (approximately 13 percent of the total hazard ratio).

This exceedance of the ERPG-3 criterion for the nearest noninvolved worker population would not be expected to result in irreversible health effects or place these workers in a life-threatening situation for the following reasons.

- ERPG-3 is defined as a concentration in which a receptor can be exposed for 1 hour without irreversible health effects. Because the Hanford Site has an in-place emergency response plan designed to evacuate workers within

1 hour of an accident, workers would be expected to evacuate their location and move to an area where potential exposures would be well below ERPG-3. Therefore, this worker population would not be exposed to airborne concentrations that would be either life threatening or result in irreversible health effects.

- The estimated air concentrations of chemicals as a result of this accident were based on very conservative meteorology, which results in movement of a plume directly toward the worker population at a relatively slow rate with minimal wind dispersion. If less conservative meteorological parameters were used, wind dispersion would cause the estimated air concentrations of chemicals to be substantially less, and the ERPG-3 criterion would not be exceeded.
- Only the bounding toxic chemical evaluation exceeded ERPG-3, while the nominal evaluation was well below 1.00E+00 for ERPG-3, suggesting that the noninvolved worker population would not receive an exposure that would result in any permanent health effects.

The cumulative acute hazard ratio for the next nearest noninvolved worker population, composed of 1,500 people and located 1,780 m (5,840 ft) away, was 2.15E+00 for ERPG-2, indicating that reversible acute health effects would be expected. The cumulative acute hazard ratio for the MEI general public was 1.76E+00 for ERPG-2, indicating that reversible acute health effects would be expected.

Corrosive/Irritant Impact from Chemical Exposure

Under nominal conditions (Table E.2.2.18), the cumulative acute hazard ratios for the MEI worker, MEI noninvolved worker and nearest noninvolved worker (335 workers at 290 m [950 ft]) were 2.47E+01, 5.10E+02 and 1.85E+00, respectively, for ERPG-3, indicating the potential for irreversible health effects that could be life threatening. These ratios were almost entirely attributable to sodium, which was assumed to be equivalent to sodium hydroxide in corrosive/irritant effects.

As discussed previously, this exceedance of the ERPG-3 criterion would not be expected to result in irreversible or life threatening health effects.

For the next nearest noninvolved worker population (1,500 workers at 1,780 m [5,840 ft]), the cumulative acute hazard ratio was 1.20E+00 for ERPG-1, indicating that only mild, irreversible irritant effects would be anticipated. For the MEI general public, the cumulative acute hazard ratio was less than 1.0 for all ERPGs, and no acute health effects would be expected.

Under bounding conditions, the cumulative acute hazard ratios for the MEI noninvolved worker and nearest noninvolved worker (335 workers at 290 m [950 ft]) were 7.31E+02 and 2.65E+00, respectively for ERPG-3, indicating the potential for irreversible health effects that could be life threatening. These acute hazard ratios were primarily attributable to:

- Sodium (approximately 83 percent of the total hazard ratio); and
- Calcium (approximately 10 percent of the total hazard ratio).

As discussed previously, this exceedance of the ERPG-3 criterion would not be expected to result in irreversible or life threatening health effects.

For the next nearest noninvolved worker and MEI general public, the cumulative acute hazard ratios were 1.74E+00 and 1.42E+00, respectively, for ERPG-1, indicating that only mild, transient irritant effects would be expected.

Under both nominal and bounding conditions, the probability of a seismic event is 3.64E-03.

E.8.4 OCCUPATION INJURIES, ILLNESSES, AND FATALITIES FROM OPERATIONS

The number of operation personnel to support the Ex Situ Extensive Separations alternative was estimated (Jacobs 1996) and summarized as follows:

- Retrieval operations - 3.74E+04 person-years; and

- Vitrification operations - 6.95E+03 person-years.

The total recordable injuries and illnesses, lost workday cases, and fatalities were calculated as follows:

Total Recordable Cases = (4.44E+04 person-years) · (2.2E+00 incidences/100 person-years) = 9.76E+02

Lost Workday Cases = (4.44E+04 person-years) · (1.1E+00 incidences/100 person-years) = 4.88E+02

Fatalities = (4.44E+04 person-years) · (3.20E-03 fatalities/100 person-years) = 1.42E+00

E.8.5 POST-REMEDIATION ACCIDENT

E.8.5.1 Deflagration in Storage Tank

After 99 percent of the tank waste has been removed from each tank, the probability of a tank generating enough hydrogen to exceed the LFL is considered to be incredible.

Consequences of Gas Building Up Under the Asphalt Barrier

If the hydrogen gas generated in the tanks was able to permeate from the tank through leaks and cracks, it could potentially build up under the asphalt layer of the Hanford Barrier if the permeation rate through the asphalt is slower than the rate in which it reaches the asphalt. Because hydrogen is highly diffusible, it is extremely unlikely that this would be the case. However, if hydrogen did build up under the asphalt layer, the worst credible consequences would result in the asphalt cracking and allowing an increased movement of the residual tank waste into the groundwater. This event could be mitigated by placing catalytic recombiners under the asphalt that would recombine hydrogen and oxygen or venting the asphalt layer.

E.8.5.2 Seismic Induced Rupture of Stabilized Tanks

As discussed in Section E.4.4.2, displacement on a fault that would increase exposure to the waste after remediation is considered incredible. The tanks would most likely crack, allowing increased infiltration to the groundwater.

E.8.6 SUMMARY OF ACCIDENTS

The potential consequences from nonradiological and nonchemical accidents that include occupational and transportation impacts are summarized in Table E.8.6.1. The LCFs associated with representative accidents for each component of the alternative are summarized in Table E.8.6.2 along with the probability of the accident. The chemical hazards associated with representative accidents for each component of the alternative are summarized in Table E.8.6.3. The chemical hazard is expressed as an exceedance of the ERPG threshold values.

Table E.8.6.1 Summary of Potential Nonradiological/Nonchemical Accident Consequences

Table E.8.6.2 Summary of Potential Radiological Accident Consequences

Table E.8.6.3 Chemical Exposures Resulting from Potential Operations and Transportation Accidents

E.9.0 EX SITU/IN SITU COMBINATION 1 ALTERNATIVE

The Ex Situ/In Situ Combination 1 alternative is a combination of the Ex Situ Intermediate Separations alternative and the In Situ Fill and Cap alternative. It would involve the ex situ treatment and disposal of some waste and in situ treatment of the remaining waste. This section analyzes and compares the construction, operation, and transportation risks associated with this alternative.

E.9.1 CONSTRUCTION ACCIDENTS

The construction activities associated with the Ex Situ/In Situ Combination1 alternative are discussed in Appendix B of the EIS. It should be noted there are no radiological or chemical consequences associated with construction accidents. Occupational injuries, illnesses, and fatalities resulting from potential construction accidents are calculated as follows.

The number of construction personnel to support the Ex Situ/In Situ Combination 1 alternative was estimated at an average of 2.07E+04 person-years (Jacobs 1996).

The total recordable injuries and illnesses, lost workday cases, and fatalities were calculated using the incidence rates from Table E.1.2.1 of this appendix as follows:

Total Recordable Cases = (2.07E +04 person-years) · (9.75E+00 incidences/100 person-years) = 2.02E +03

Lost Workday Cases = (2.07E +04 person-years) · (2.45E+00 incidences/100 person-years) = 5.08E +02

Fatalities = (2.07E +04 person-years) · (3.20E-03 fatalities/100 person-years) = 6.63E -01

E.9.2 TRANSPORTATION ACCIDENTS

Transportation activities associated with this alternative are:

- Transporting residual SST waste to a vitrification facility;
- Transporting earthen material from onsite borrow site to fill tank voids;
- Transporting earthen material from onsite borrow site for Hanford Barrier;
- Transporting construction material to the Hanford Site; and
- Employees commuting to work each day.

E.9.2.1 Radiological Consequences

The methodology for determining radiological consequences from accidents while transporting HLW onsite and offsite was previously discussed in Section E.6.2.1.

The receptor dose and LCF risk resulting from the accident analysis for retrieval of SST residuals is presented in Table E.9.2.1 for the integrated population and Table E.9.2.2 for the MEI worker and MEI general public. The MUST waste would not be retrieved in this alternative.

Table E.9.2.1 Integrated Radiological Impact from Retrieval Transport Accidents

Table E.9.2.2 Maximally-Exposed Individual Radiological Impact from Retrieval Transport Accidents

There would be no LCFs resulting from an accident while transporting retrieved waste onsite.

E.9.2.2 Chemical Exposure

The same chemicals would be transported to the Hanford Site by truck and rail as in the Ex Situ Intermediate Separations alternative. Therefore, the chemical exposure resulting from an accident would be the same as that shown in Table E.6.2. 3 for Ex Situ Intermediate Separations alternative.

However, there would be 50 percent fewer shipments, which equates to a 50 percent reduction in the probability of an accident.

The general public exposure to anhydrous ammonia would exceed the ratio of exposure to ERPG-3 by 1.24E+01 and sodium hydroxide would exceed the ratio of exposure to ERPG-1 by 2.45E+00 for corrosive/irritant chemicals. Consequently, this exposure to the MEI general public could potentially result in lethal effects.

E.9.2.3 Occupational Injuries and Fatalities

Truck and Rail Transportation

Injuries and fatalities resulting from direct impact of transportation accidents are analyzed in this subsection. Rail and truck transportation activities to transport material and supplies to the Site for this alternative were estimated by combining a fraction (50 percent of retrieval, 50 percent of vitrification, and 40 percent of closure) of the data values in the extensive retrieval engineering data package (WHC 1995j) with a fraction (60 percent of closure) of the data values for In Situ Fill and Cap in the in situ vitrification engineering data package (WHC 1995f). The results are summarized in Table E.9.2. 3 .

Table E.9.2.3 Summary of Transportation Activities for the Ex Situ/In Situ Combination Alternative

The number of injuries and fatalities were calculated by multiplying the total distance traveled in each zone shown in Table E.9.2. 4 by the appropriate unit risk factors shown in Table E.1.3.1. The distance traveled in the population zones were calculated using the methodology previously discussed in Section E.1.3.

Table E.9.2.4 Distance Traveled in Population Zones for the Ex Situ/In Situ Combination Alternative

The expected injuries and fatalities resulting from transportation accidents associated with the Ex Situ/In Situ Combination alternative are summarized in Table E.9.2. 5 .

Table E.9.2.5 Fatalities and Injuries Resulting from Truck and Rail Transportation Accidents for the Ex Situ/In Situ Combination Alternative

Employee Traffic

In addition to transporting materials and supplies to and from the Hanford Site by truck and rail, site workers and other personnel required to perform the various activities would be driving to the site in their vehicles. The total person-years to perform the activities was estimated at 7.32E +04. This number was estimated by combining 60 percent of the employee vehicle miles from the Ex Situ Intermediate Separations alternative with 60 percent of the employee vehicle miles from the In Situ Fill and Cap alternative.

Each person was assumed to work 260 days of the year. The round-trip distance traveled to work from the Tri-Cities area was estimated at 140 km (87 mi) with an estimated 1.35 passengers per vehicle (DOE 1994a). From the information listed previously the total employee vehicle distance was calculated as follows:

(7.32E +04 person-years) · (260 days/year) · (140 km/day) · (1/1.35 passengers per vehicle) =
1.97E+ 09 km (1.22E+09 mi)

To calculate the expected number of injuries and fatalities resulting from vehicle accidents, the injury/fatality rates discussed in Section E.1.3 were used. The expected number of injuries and fatalities resulting from employee vehicle accidents were calculated as follows:

Injuries = (1.97E +09 km) · (7.1E-07 injuries/km) = 1.41E +03

Fatalities = (1.97E +09 km) · (8.98E-09 fatalities/km) = 1.77E+01

Cumulative Transportation Injuries and Fatalities

The cumulative nonradiological and nontoxicological injuries and fatalities incurred as a direct result of traffic accident impacts are the sum of the truck and rail transport and employee vehicle accidents. The results are summarized in Table E.9.2. 6 .

Table E.9.2.6 Cumulative Injuries and Fatalities from Traffic Impacts for the Ex Situ/In Situ Combination Alternative

E.9.3 OPERATION ACCIDENTS

The radiological and chemical operation accidents for the Ex Situ/In Situ Combination 1 alternative are the same as the Ex Situ Intermediate Separations alternative and the In Situ Fill and Cap alternative. The radiological cancer risk and the chemical exposure would be bound by the Ex Situ Intermediate Separations alternative presented in Section E.6.3 and are summarized as follows.

E.9.3.1 Routine Operation - Mispositioned Jumper Accident - Tank Waste Transfer

The dominant routine operations accident during waste transfer is the mispositioned jumper accident previously discussed in the No Action alternative in Section E.2.2.1 and are summarized as follows:

Source-Term - The source-term resulting from a spray release in Section E.2.2.1.1 was calculated to be 52 L (14 gal).

Probability - The frequency of a mispositioned jumper in Section E.2.2.1.2 was 1.1E-02 per year. The Ex Situ/In Situ Combination 1 alternative was based on 18.5 years of operations; therefore, the probability was calculated to be 2.0E-01.

Radiological Consequences - The radiological consequences presented in Table E.2.2.2 are reproduced in Table E.9.3.1.

Table E.9.3.1 Dose Consequence from Mispositioned Jumper

Radiological Cancer Risk - The LCFs calculated in Section E.2.2.1.4 are the same for the Ex Situ/In Situ Combination 1 alternative; however, the LCF risk (point estimate) is not the same due to the difference in probabilities. The LCFs and the LCF risk are calculated in Table E.9.3.2. The bounding scenario calculations show that all 10 would potentially receive a fatal dose and assumably die directly after exposure if the accident occurred. There would be approximately seven LCFs from the noninvolved worker population and 2 from the general public. The nominal scenario calculations show there would be no LCFs.

Table E.9.3.2 Latent Cancer Fatality Risk from Mispositioned Jumper

Chemical Consequences

Potential acute hazards associated with a mispositioned jumper are identical to those summarized in Tables E.2.2.4 (toxic chemicals, nominal conditions), E.2.2.5 (toxic chemicals, bounding conditions), E.2.2.6 (corrosive/irritant chemicals, nominal conditions) and E.2.2.7 (corrosive/irritant chemicals, bounding conditions) for the No Action alternative.

Toxic Impact from Chemical Exposure

Under nominal conditions (Table E.2.2.4), the cumulative acute hazard ratios for the MEI worker, MEI noninvolved worker and MEI general public were less than 1.0, indicating that no adverse acute health effects would be expected for these three receptors. Under bounding conditions (Table E.2.2.5), the MEI worker was not evaluated because death would occur from exposure to radionuclides. The cumulative acute hazard ratio for the MEI noninvolved worker was 5.36E+00 for ERPG-2, indicating that reversible acute health effects would be expected. This acute hazard ratio was primarily attributable to mercury (approximately 89 percent of the overall hazard ratio). No adverse acute health effects were predicted for the MEI general public under bounding conditions.

Corrosive/Irritant Impact from Chemical Exposure

Under nominal conditions (Table E.2.2.6), the cumulative acute hazard ratio for the MEI worker was 2.70E+00 for ERPG-3, indicating the potential for irreversible health effects that could be life threatening. This acute hazard ratio was almost entirely attributable to sodium assumed to be equivalent to sodium hydroxide in corrosive/irritant effects. For the MEI noninvolved worker, the cumulative acute hazard ratio for ERPG-1 was 3.00E+00, indicating that only mild reversible irritant effects would be expected. No acute health impacts were predicted for the MEI general public under nominal conditions. Under bounding conditions (Table E.2.2.7), the MEI worker was not evaluated because death would occur from exposure to radionuclides. For the MEI noninvolved worker, the cumulative acute hazard ratio for ERPG-1 was 4.36E+00, indicating that only mild reversible irritant effects would be expected. No acute health impacts were predicted for the MEI general public under bounding conditions.

Under both nominal and bounding conditions, the probability of a mispositioned jumper is 2.04E-01.

E.9.3.2 Continued Operations Accident - Waste Storage Tanks

The dominant accident is a hydrogen deflagration in a waste storage tank previously discussed in the No Action alternative in Section E.2.2.2.1 and is summarized as follows:

Source-Term - The source-term resulting from the fire in Section E.2.2.2.1 was calculated to be 2.4 L (0.6 gal).

Probability - The frequency of the hydrogen deflagration in a waste storage tank in Section E.2.2.2.2 was estimated to be 7.2E-03 per year. The probability of the scenario based on 26 years of operation was therefore estimated to be 1.9E-01.

Radiological Consequences - The radiological consequences presented in Table E.2.2.8 are reproduced in Table E.9.3.3.

Table E.9.3.3 Dose Consequence from Hydrogen Deflagration in Waste Storage Tank

Radiological Cancer Risk - The LCFs calculated in Section E.2.2.2.4 are reproduced in Table E.9.3.4.

Table E.9.3.4 Latent Cancer Fatality Risk from Hydrogen Deflagration in Waste Storage Tank

In the bounding scenario all 10 workers would potentially receive a fatal dose and assumably die directly after the exposure. There would also be 10 LCFs attributed to the exposure to the noninvolved workers and 2 LCFs to the general public if the accident occurred. The nominal scenario calculations show there would be no LCFs.

Chemical Consequences

Potential acute hazards associated with a hydrogen burn in a waste storage tank are identical to those summarized in Tables E.2.2.10 (toxic chemicals, nominal conditions), E.2.2.11 (toxic chemicals, bounding conditions), E.2.2.12 (corrosive/irritant chemicals, nominal conditions) and E.2.2.13 (corrosive/irritant chemicals, bounding conditions) for the No Action alternative.

Under bounding conditions, chemical impacts were not evaluated for the MEI worker because all workers would receive a lethal radiation dose as discussed previously.

Toxic Impact from Chemical Exposure

Under nominal conditions (Table E.2.2.10), the cumulative acute hazard ratio for the MEI worker was 1.57E+00 for ERPG-2, indicating that reversible acute health effects would be expected. This acute hazard ratio was primarily attributable to TOC (approximately 87 percent of the overall ERPG-2 ratio). The TOC is assumed to be equivalent in toxicity to tributylphosphate, which is the most acutely toxic constituent of the organic analytes identified. Tributylphosphate was used as a surrogate because an inventory of the various chemicals that make up the TOC class is not available. For the MEI noninvolved worker, the cumulative acute hazard ratio for ERPG-3 was 9.38E+00, indicating the potential for irreversible health effects that could be life threatening. This acute hazard ratio was also primarily attributable to TOC (approximately 90 percent of the overall ERPG-3 ratio) However, the MEI noninvolved worker is a hypothetical worker assumed to be located 100 m (330 ft) from the source area. The nearest noninvolved worker population is located 290 m (950 ft) from the source area and had no cumulative acute hazard ratios greater than 1.0 for any of the ERPGs, indicating that no acute health effects would be expected for the nearest noninvolved worker population. Likewise, no acute health effects were predicted for the MEI general public under nominal conditions.

Under bounding conditions (Table E.2.2.11), the cumulative acute hazard ratio for the MEI noninvolved worker was 4.54E+02 for ERPG-3, indicating the potential for irreversible health effects that could be life-threatening. This acute hazard ratio is primarily attributable to:

- Oxalate (approximately 37 percent of the total hazard ratio);
- Beryllium (approximately 13 percent of the total hazard ratio);
- Cadmium (approximately 14 percent of the total hazard ratio);
- Uranium (approximately 12 percent of the total hazard ratio); and
- TOC (approximately 8 percent of the total hazard ratio).

As discussed previously, this is a hypothetical receptor located 100 m (330 ft) from the source. The cumulative acute hazard ratio for the nearest noninvolved worker population located 290 m (950 ft) from the source was 1.65E+00 for ERPG-3, indicating the potential for irreversible health effects that could be life threatening for 335 workers. This hazard ratio was attributable to the same toxic chemicals listed above. This exceedance of the ERPG-3 criterion for the nearest noninvolved worker population would not be expected to result in irreversible health effects or place these workers in a life-threatening situation for the following reasons.

- ERPG-3 is defined as a concentration in which a receptor can be exposed for 1 hour without irreversible health effects. Because the Hanford Site has an in-place emergency response plan designed to evacuate workers within 1 hour of an accident, workers would be expected to evacuate their location and move to an area where potential exposures would be well below ERPG-3. Therefore, this worker population would not be exposed to airborne concentrations that would be either life threatening or result in irreversible health effects.
- The estimated air concentrations of chemicals as a result of this accident were based on very conservative meteorology, which results in movement of a plume directly toward the worker population at a relatively slow rate with minimal wind dispersion. If less conservative meteorological parameters were used, wind dispersion would cause the estimated air concentrations of chemicals to be substantially less, and the ERPG-3 criterion would not be exceeded.
- Only the bounding toxic chemical evaluation exceeded ERPG-3, while the nominal evaluation was well below 1.00E+00 for ERPG-3, suggesting that the noninvolved worker population would not receive an exposure that would result in any permanent health effects.

The next nearest noninvolved worker population is located 1,780 m (5,840 ft) from the source and contains 1,500 workers. The cumulative acute hazard ratio was less than 1.0 for all ERPGs, indicating that no acute health effects would be expected for this population of workers. No acute health impacts were predicted for the MEI general public.

Corrosive/Irritant Impact from Chemical Exposure

Under nominal conditions (Table E.2.2.12), the cumulative acute hazard ratio for the MEI worker was 3.82E+00 for ERPG-3, indicating the potential for irreversible corrosive/irritant effects that could be life threatening. For the MEI noninvolved worker, the cumulative acute hazard ratio for ERPG-3 was 7.89E+01 and would indicate irreversible corrosive/irritant effects that could be life threatening for this hypothetical receptor. This hazard ratio was primarily attributable to sodium, which was assumed to be equivalent to sodium hydroxide in corrosive/irritant effects. For the nearest noninvolved worker population (290 m [950 ft]) composed of 335 workers, the cumulative acute hazard ratio for ERPG-1 was 1.38E+01, indicating that only mild reversible effects would be expected. No acute health impacts were predicted for the MEI general public under nominal conditions.

Under bounding conditions (Table E.2.2.13), the cumulative acute hazard ratio for the MEI noninvolved worker was 1.91E+02 for ERPG-3, indicating irreversible health effects that could be life threatening for this hypothetical receptor. This hazard ratio was primarily attributable to :

- Sodium as sodium hydroxide (approximately 75 percent of the total hazard ratio);
- Chromium (approximately 14 percent of the total hazard ratio); and
- Calcium (approximately 6 percent of the total hazard ratio).

For the nearest noninvolved worker population (290 m [950 ft]) composed of 335 workers, the cumulative acute hazard ratio was 1.74E+00 for ERPG-2, indicating that reversible acute effects would be expected. No acute health impacts were predicted for the MEI general public under nominal conditions.

Under both nominal and bounding conditions, the probability of a hydrogen deflagration event in a waste storage tank is 1.87E-01.

E.9.3. 3 Retrieval - Loss of Filtration Accident

The dominant retrieval operations accident is the loss of filtration accident previously discussed in the Ex Situ Intermediate Separations alternative in Section E.6.3. 3 and is summarized as follows:

Source-Term - The source-term resulting from the airborne release in Section E.6.3. 3 .1 was calculated to be 2.5E-01 L (6.6E-02 gal).

Probability - The frequency of a loss of filtration in section E.6.3. 3 .2 was 8.8E-06 per year. The Ex Situ/In Situ Combination retrieval activity was based on 2 6 years of operations; therefore, the probability was calculated to be 2.3E-04.

Radiological Consequences - The radiological consequences presented in Section 6.3. 3 .3 are reproduced in Table E.9.3. 5 .

Table E.9.3.5 Dose Consequence from Loss of Filtration

Radiological Cancer Risk - The LCFs and the LCF point estimate risk were calculated for the receptors and are presented in Table E.9.3.6 .

Table E.9.3.6 Latent Cancer Fatality Risk from Loss of Filtration

In the bounding scenario all 10 workers would potentially receive a fatal dose and assumably die directly after the exposure. T he calculations show there would be nine LCFs attributed to the exposure to the noninvolved workers and two LCFs to the general public if the accident occurred. The nominal scenario calculations show there would be no LCFs.

Chemical Consequences

The chemical exposure to the receptors from the postulated accident was calculated in Appendix A of the accident data package (Shire et al. 1995 and Jacobs 1996) and summarized in the exposure column in Tables E.6.3.8 and E.6.3.9 for the nominal and bounding toxic effects, respectively, and Tables E.6.3.10 and E.6.3.11 for the nominal and bounding corrosive/irritant effects, respectively. The tables compare the concentration of postulated chemical releases to acute exposure criteria (ERPGs) discussed in Section 1.1.7.

Under bounding conditions, chemical impacts were not evaluated for the MEI worker because all workers would receive a lethal radiation dose, as discussed previously.

Toxic Impact from Chemical Exposure

Under nominal conditions (Table E.6.3.8), the cumulative acute hazard ratio for the MEI worker was less than 1.0 for all ERPGs, indicating that no adverse acute health effects would be expected. For the MEI noninvolved worker, the cumulative acute hazard ratio was 1.84E+00 for ERPG-1, indicating that only mild, transient acute health effects would be expected. No acute health effects were predicted for the MEI general public under nominal conditions.

Under bounding conditions (Table E.6.3.9), the cumulative acute hazard ratio for the MEI noninvolved worker was 7.27E+01 for ERPG-3, indicating the potential for irreversible health effects that could be life-threatening. This acute hazard ratio is primarily attributable to:

- Uranium (approximately 48 percent of the total hazard ratio);
- Oxalate (approximately 24 percent of the total hazard ratio);
- Mercury (approximately 13 percent of the total hazard ratio); and
- TOC (approximately 7 percent of the total hazard ratio).

As discussed previously, this is a hypothetical receptor located 100 m (330 ft) from the source. The cumulative acute hazard ratio for the nearest noninvolved worker population (335 workers) located 290 m (950 ft) from the source was 5.40E+00 for ERPG-2, indicating that reversible acute health effects would be expected. No acute health impacts were predicted for the MEI general public.

Corrosive/Irritant Impact from Loss of Filtration

Under nominal conditions (Table E.6.3.10), the cumulative acute hazard ratio for the MEI worker was 2.11E+00 for ERPG-2, indicating that reversible corrosive/irritant effects would be expected. For the MEI noninvolved worker, the cumulative acute hazard ratio for ERPG-3 was 1.72E+01 and would indicate irreversible corrosive/irritant effects that could be life threatening for this hypothetical receptor. This hazard ratio was primarily attributable to sodium, which was assumed to be equivalent to sodium hydroxide in corrosive/irritant effects. For the nearest noninvolved worker population (290 m [950 ft]) composed of 335 workers, the cumulative acute hazard ratio for ERPG-1 was 3.02E+00, indicating that only mild, transient irritant effects would be expected. No acute health impacts were predicted for the MEI general public under nominal conditions.

Under bounding conditions (Table E.6.3.11), the cumulative acute hazard ratio for the MEI noninvolved worker was 2.47E+01 for ERPG-3, indicating irreversible health effects that could be life threatening for this hypothetical receptor. This hazard ratio was primarily attributable to :

- Sodium as sodium hydroxide (approximately 82 percent of the total hazard ratio); and
- Calcium (approximately 9 percent of the total hazard ratio).

For the nearest noninvolved worker population (290 m [950 ft]) composed of 335 workers, the cumulative acute hazard ratio was 4.38E+00 for ERPG-1, indicating that only mild, transient irritant effects would be expected. No acute health impacts were predicted for the MEI general public under nominal conditions.

Under both nominal and bounding conditions, the probability of a loss of filtration event in a waste storage tank is 2.29E-04.

E.9.3. 4 Pretreatment - Seismic Induced Line Break in Vault

The dominant pretreatment operations accident is the seismic-induced line break in vault accident previously discussed in the Ex Situ Intermediate Separations alternative in Section E.6.3. 4 and is summarized as follows:

Source-Term - The source-term resulting from the airborne release in Section E.6.3. 4 .1 was calculated to be 7.3E-02 L (1.9E-02 gal).

Probability - The annual exceedance frequency of the seismic event in Section E.6.3. 4 .2 was 6.5E-04 per year. The Ex Situ/In Situ Combination 1 alternative was based on 2 6 years of operations: therefore, the probability was calculated to be 1.7E-02.

Radiological Consequences - The radiological consequences presented in Section 6.3. 4 .3 are reproduced in Table E.9.3. 7 .

Table E.9.3.7 Dose Consequence from Seismic Induced Line Break in Vault

Radiological Cancer Risk - The LCFs and the LCF point estimate risk were calculated for the receptors and presented in Table E.9.3.8 . The calculations show there would be no LCFs attributable to this exposure if the accident occurs for the bounding and nominal scenarios .

Table E.9.3.8 Latent Cancer Fatality Risk from Seismic-Induced Line Break in Vault

Chemical Consequences

The chemical exposure to the receptors from the postulated accident was calculated in Appendix A of the accident data package (Shire et al. 1995 and Jacobs 1996) and summarized in the exposure column in Tables E.6.3.14 and E.6.3.15 for the nominal and bounding toxic effects, respectively, and Tables E.6.3.16 and E.6.3.17 for the nominal and bounding corrosive/irritant effects, respectively. The tables compare the concentration of postulated chemical releases to acute exposure criteria (ERPGs) discussed in Section 1.1.7.

Toxic Impact from Chemical Exposure

Under nominal conditions (Table E.6.3.14), the cumulative acute hazard ratios for the MEI worker, MEI noninvolved worker and MEI general public were less than 1.0, indicating that no adverse acute health effects would be expected for these three receptors. Under bounding conditions (Table E.6.3.15), the cumulative acute hazard ratios for the MEI worker, MEI noninvolved worker, and MEI general public were less than 1.0, indicating that no adverse acute health effects would be expected for these three receptors.

Corrosive/Irritant Impact from Chemical Exposure

Under nominal conditions (Table E.6.3.16), the cumulative acute hazard ratios for the MEI worker, MEI noninvolved worker and MEI general public were less than 1.0, indicating that no adverse acute health effects would be expected for these three receptors. Under bounding conditions (Table E.6.3.17), the cumulative acute hazard ratios for the MEI worker, MEI noninvolved worker, and MEI general public were less than 1.0, indicating that no adverse acute health effects would be expected for these three receptors.

Under both nominal and bounding conditions, the probability of a pretreatment spray release is 1.69E-02.

E.9.3. 5 Treatment (Ex Situ Vitrification) - Canister of Vitrified High-Level Waste Inadvertently Drops and Ruptures

The dominant immobilization operations accident is the "canister of vitrified HLW inadvertently drops and ruptures" accident previously discussed in the Ex Situ Intermediate Separations alternative in Section E.6.3.5 and is summarized as follows:

Source-Term - The source-term resulting from the airborne release in Section E.6.3. 5 .1 was calculated to be 2.5E-06 g (8.8E-08 oz).

Probability - The frequency of the accident in Section E.6.3. 5 .2 was 6.0E-01 per year. The Ex Situ/In Situ Combination alternative was based on 2 6 years of operations; therefore, the probability was calculated to be 1.0E+00.

Radiological Consequences - The radiological consequences presented in Section 6.3. 5 .3 are reproduced in Table E.9.3. 9 .

Table E.9.3.9 Dose Consequence from Breached Canister

Radiological Cancer Risk - The LCFs and the LCF point estimate risk were calculated for the receptors and presented in Table E.9.3.10 . The calculations show there would be no LCFs attributable to this exposure if the accident occurs for the bounding and nominal scenarios.

Table E.9.3.10 Latent Cancer Fatality Risk from Breached Canister

Chemical Consequences - No chemical consequences were evaluated (Shire et al. 1995 and Jacobs 1996) since the release would be through two-stage HEPA filters that would reduce the source-term well below the cumulative ratio of exposure to ERPG-1 values for toxic or corrosive/irritant chemicals.

E.9.3. 6 Treatment - In Situ Fill and Cap

The dominant treatment operations accident is the tank deflagration accident resulting in a tank dome collapse previously discussed in the In Situ Fill and Cap alternative in Section E.4.3. 3 and is summarized as follows:

Source-Term - The source-term resulting from the airborne release in Section E.4.3. 3 .1 was calculated to be 7.5 L (2.0 gal).

Probability - The probability of a tank dome collapse in Section E.4.3. 3 .2 was assumed to be 1.0E-04.

Radiological Consequences - The radiological consequences presented in Section 4.3. 3 .3 are reproduced in Table E.9.3. 11 .

Table E.9.3.11 Dose Consequence from Tank Dome Collapse Due to Deflagration

Radiological Cancer Risk - The LCFs and the LCF point estimate risk were calculated for the receptors and presented in Table E.9.3.12 .

Table E.9.3.12 Latent Cancer Fatality Risk from Tank Dome Collapse Due to Deflagration

In the bounding scenario all 10 workers would potentially receive a fatal dose and assumably die directly after the exposure. The calculations show there would be 11 LCFs attributed to the exposure to the noninvolved workers and 2 LCFs to the general public if the accident occurred. The nominal scenario calculations show there would be no LCFs.

E.9.3. 6 .1 Chemical Consequences of Tank Dome Collapse

The chemical exposure to the receptors from the postulated accident was identical to that summarized in the exposure column in Tables E.4.3.8 and E.4.3.9 for the nominal and bounding toxic effects, respectively, and Tables E.3.4.10 and E.3.4.11 for the nominal and bounding corrosive/irritant effects, respectively. The tables compare the concentration of postulated chemical releases to acute exposure criteria (ERPGs) discussed in Section 1.1.7.

Under bounding conditions, chemical impacts were not evaluated for the MEI worker because all workers would receive a lethal radiation dose, as discussed previously.

Toxic Impact from Chemical Exposure

Under nominal conditions (Table E.4.3.8), the cumulative acute hazard ratio for the MEI worker was 2.64E+00 for ERPG-1, indicating that only mild transient effects would be expected. For the MEI noninvolved worker, the cumulative acute health hazard was 2.59E+00 for ERPG-3, indicating the potential for irreversible health effects that could be life threatening. This acute hazard ratio was primarily attributable to TOC (approximately 84 percent of the total hazard ratio). The TOC is assumed to be equivalent in toxicity to tributylphosphate, which is the most acutely toxic constituent of the organic analytes identified. Tributylphosphate was used as a surrogate because an inventory of the various chemicals that make up the TOC class is not available. The cumulative acute hazard ratio, for the nearest noninvolved worker population (consisting of 335 workers located 290 m [950 ft] away) was less than 1.0 for all ERPGs, suggesting that no acute health effects would be expected.

Under bounding conditions (Table E.4.3.9), the cumulative hazard ratios for the MEI and nearest noninvolved worker (335 workers located 290 m [950 ft] away) were 2.15E+03 and 7.80E+00 for ERPG-3, respectively. These ratios were primarily attributable to:

- Uranium (approximately 47 percent of the total hazard ratio);
- Oxalate (approximately 24 percent of the total hazard ratio); and
- Mercury (approximately 13 percent of the total hazard ratio).

This exceedance of the ERPG-3 criterion for the nearest noninvolved worker population would not be expected to result in irreversible health effects or place these workers in a life-threatening situation for the following reasons.

- ERPG-3 is defined as a concentration in which a receptor can be exposed for 1 hour without irreversible health effects. Because the Hanford Site has an in-place emergency response plan designed to evacuate workers within 1 hour of an accident, workers would be expected to evacuate their location and move to an area where potential exposures would be well below ERPG-3. Therefore, this worker population would not be exposed to airborne concentrations that would be either life threatening or result in irreversible health effects.
- The estimated air concentrations of chemicals as a result of this accident were based on very conservative meteorology, which results in movement of a plume directly toward the worker population at a relatively slow rate with minimal wind dispersion. If less conservative meteorological parameters were used, wind dispersion would cause the estimated air concentrations of chemicals to be substantially less, and the ERPG-3 criterion would not be exceeded.
- Only the bounding toxic chemical evaluation exceeded ERPG-3, while the nominal evaluation was well below 1.00E+00 for ERPG-3, suggesting that the noninvolved worker population would not receive an exposure that would result in any permanent health effects.

The cumulative acute hazard ratio for the next nearest noninvolved worker population, composed of 1,500 people and located 1,780 m (5,840 ft) away, was 2.15E+00 for ERPG-2, indicating that reversible acute health effects would be expected. The cumulative acute hazard ratio for the MEI general public was 1.76E+00 for ERPG-2, indicating that reversible acute health effects would be expected.

Corrosive/Irritant Impact from Chemical Exposure

Under nominal conditions (Table E.3.4.10), the cumulative acute hazard ratios for the MEI worker, MEI noninvolved worker and nearest noninvolved worker (335 workers at 290 m [950 ft]) were 2.47E+01, 5.10E+02 and 1.85E+00, respectively, for ERPG-3, indicating the potential for irreversible health effects that could be life threatening. These ratios were almost entirely attributable to sodium, which was assumed to be equivalent to sodium hydroxide in corrosive/irritant effects. For the next nearest noninvolved worker population (1,500 workers at 1,780 m [5,840 ft]), the cumulative acute hazard ratio was 1.20E+00 for ERPG-1, indicating that only mild irreversible irritant effects would be anticipated. For the MEI general public, the cumulative acute hazard ratio was less than 1.0 for all ERPGs, and no acute health effects would be expected.

Under bounding conditions (Table E.4.3.11), the cumulative acute hazard ratios for the MEI noninvolved worker and nearest noninvolved worker (335 workers at 290 m [950 ft]) were 7.31E+02 and 2.65E+00, respectively for ERPG-3, indicating the potential for irreversible health effects that could be life threatening. These acute hazard ratios were primarily attributable to:

- Sodium (approximately 83 percent of the total hazard ratio); and
- Calcium (approximately 10 percent of the total hazard ratio).

As discussed previously, this exceedance of the ERPG-3 criterion would not be expected to result in irreversible or life threatening health effects.

For the next nearest noninvolved worker and MEI general public, the cumulative acute hazard ratios were 1.74E+00 and 1.42E+00, respectively, for ERPG-1, indicating that only mild, transient irritant effects would be expected.

Under both nominal and bounding conditions, the probability of a seismic event is 1.00E-04.

E.9.3.7 Beyond Design Basis Accidents

The beyond design basis accident is a seismic event resulting in the collapse of a SST. In the event of a 0.43 g earthquake, a SST could potentially collapse (LANL 1995). This event is not dependent on the remediation alternative but has the same annual frequency regardless of the alternative that is chosen. The length of time unremediated waste would remain in tanks that have not been backfilled would vary depending on the alternative and would affect the probability of the event. The probability of the event is the product of the annual frequency of the earthquake and the number of years the waste remains untreated in the unstabilized tanks.

At smaller annual frequencies, larger earthquakes could occur resulting in greater destruction and larger numbers of LCF to the onsite and offsite populations. In addition to population exposures from the collapsed SSTs, the impact to other Hanford Site facilities and operations would potentially add to the chemical and radiological risk. This would be a severe earthquake that would cause catastrophic structural damage in the Tri-Cities and the Hanford Site with expected extensive loss of life. There would be injuries and fatalities resulting from collapsed buildings and homes, fires, and traffic accidents. However, this section evaluates the radiological and chemical impacts resulting from the collapse of one SST.

E.9.3.7.1 Source-Term Development

It was conservatively assumed that the radiological and chemical contaminants in the headspace are available for release. The collapse of a portion of the dome and overburden compresses the vapor in the headspace as it descends, enhancing the vapor release rate by a sudden pressure difference. Assuming for each tank a respirable concentration of contaminants in the headspace of 100 mg/m^3, a liquid SpG of 1.5, and a headspace volume of 1,000 m^3 (Shire et al. 1995 and Jacobs 1996), the potential source-term contribution from the headspace release was calculated as follows:

$$(100\ mg/m^3) \cdot (1\ g/1{,}000\ mg) \cdot (1\ L/1{,}000\ g) \cdot (1{,}000\ m^3) \cdot (1/1.5) = 6.67E\text{-}02\ L\ (1.8E\text{-}02\ gal).$$

It was conservatively assumed that the liquids had been pumped from the tanks so that the tanks contained only solids and the MAR was 2,500 L (660 gal) for each tank. It was postulated that the fall of the dome and overburden generated an air movement sufficient to suspend a fraction the MAR. Assuming the respirable release fraction to be 2.0E-03 (Shire et al. 1995 and Jacobs 1996), the potential source-term contribution was calculated as follows:

$$(2{,}500\ L) \cdot (2.0E\text{-}03) = 5.00E{+}00\ L\ (1.3\ gal).$$

It was postulated that prevailing winds resuspend a respirable fraction of the MAR (2,500 L [660 gal]). A respirable release fraction of 4.0E-05/hr for 24 hours was assumed. The potential source-term contribution from resuspension was calculated as follows:

$$(2{,}500\ L) \cdot (4.0E\text{-}05/hr) \cdot (24\ hr) = 2.4\ L\ (0.6\ gal).$$

The combined source-term for the acute release is calculated as follows:

(6.67E-02 L) + (5.0 L) + (2.4 L) = 7.4 L (2.0 gal).

E.9.3.7.2 Probability of a Beyond Design Basis Earthquake

This earthquake has a calculated annual exceedance frequency of approximately 1.40E-04 (WHC 1996b). The probability for this scenario based on 26 years of operation was therefore estimated to be 3.6E-3.

E.9.3.7.3 Radiological Consequences from a Beyond Design Basis Earthquake

The radiological dose to the receptors from the previous source-term was calculated by the GENII computer code (Napier et al. 1988) using the methodology previously discussed in Section E.1.1.6. The results are presented in Table E.9.3.13.

Table E.9.3.13 Dose Consequence from Seismic Event

E.9.3.7.4 Radiological Cancer Risk from a Beyond Design Basis Earthquake

The LCFs and LCF point estimate risk are presented in Table E.9.3.14

Table E.9.3.14 Latent Cancer Fatality Risk from Seismic Event

In the bounding scenario, all 10 workers would potentially receive a fatal dose and assumably die directly after the exposure. There would also be 10 LCFs attributed to the exposure to the noninvolved workers and two LCFs to the general public if the accident occurred. The nominal scenario calculations show there would be no LCFs.

E.9.3.7.5 Chemical Consequences from a Beyond Design Basis Earthquake

Potential acute hazards associated with a beyond design basis earthquake are identical to those summarized in Tables E.2.2.16 (toxic chemicals, nominal conditions), E.2.2.17 (toxic chemicals, bounding conditions), E.2.2.18 (corrosive/irritant chemicals, nominal conditions) and (corrosive/irritant chemicals, bounding conditions) for the No Action alternative.

Under bounding conditions, chemical impacts were not evaluated for the MEI worker because all workers would receive a lethal radiation dose, as described previously.

Toxic Impact from Chemical Exposure

Under nominal conditions, the cumulative acute hazard ratio for the MEI worker was 2.64E+00 for ERPG-1, indicating that only mild transient effects would be expected. For the MEI noninvolved worker, the cumulative acute health hazard was 2.59E+00 for ERPG-3, indicating the potential for irreversible health effects that could be life threatening. This acute hazard ratio was primarily attributable to TOC (approximately 84 percent of the total hazard ratio). The TOC is assumed to be equivalent in toxicity to tributylphosphate which is the most acutely toxic constituent of the organic analytes identified. Tributylphosphate was used as a surrogate because an inventory of the various chemicals that make up the TOC class is not available. The cumulative acute hazard ratio for the nearest noninvolved worker population (consisting of 335 workers located 290 m [950 ft] away) was less than 1.0 for all ERPGs, suggesting that no acute health effects would be expected.

Under bounding conditions (Table E.2.2.17), the cumulative hazard ratios for the MEI and nearest noninvolved worker (335 workers located 290 m [950 ft] away) were 2.15E+03 and 7.80E+00 for ERPG-3, respectively. These ratios were primarily attributable to:

- Uranium (approximately 47 percent of the total hazard ratio);
- Oxalate (approximately 24 percent of the total hazard ratio); and
- Mercury (approximately 13 percent of the total hazard ratio).

This exceedance of the ERPG-3 criterion for the nearest noninvolved worker population would not be expected to result in irreversible health effects or place these workers in a life-threatening situation for the following reasons.

- ERPG-3 is defined as a concentration in which a receptor can be exposed for 1 hour without irreversible health effects. Because the Hanford Site has an in-place emergency response plan designed to evacuate workers within 1 hour of an accident, workers would be expected to evacuate their location and move to an area where potential exposures would be well below ERPG-3. Therefore, this worker population would not be exposed to airborne concentrations that would be either life threatening or result in irreversible health effects.
- The estimated air concentrations of chemicals as a result of this accident were based on very conservative meteorology, which results in movement of a plume directly toward the worker population at a relatively slow rate with minimal wind dispersion. If less conservative meteorological parameters were used, wind dispersion would cause the estimated air concentrations of chemicals to be substantially less, and the ERPG-3 criterion would not be exceeded.
- Only the bounding toxic chemical evaluation exceeded ERPG-3, while the nominal evaluation was well below 1.00E+00 for ERPG-3, suggesting that the noninvolved worker population would not receive an exposure that would result in any permanent health effects.

The cumulative acute hazard ratio for the next nearest noninvolved worker population, composed of 1,500 people and located 1,780 m (5,840 ft) away, was 2.15E+00 for ERPG-2, indicating that reversible acute health effects would be expected. The cumulative acute hazard ratio for the MEI general public was 1.76E+00 for ERPG-2, indicating that reversible acute health effects would be expected.

Corrosive/Irritant Impact from Chemical Exposure

Under nominal conditions (Table E.2.2.18), the cumulative acute hazard ratios for the MEI worker, MEI noninvolved worker, and nearest noninvolved worker (335 workers at 290 m [950 ft]) were 2.47E+01, 5.10E+02 and 1.85E+00, respectively, for ERPG-3, indicating the potential for irreversible health effects that could be life threatening. These ratios were almost entirely attributable to sodium, which was assumed to be equivalent to sodium hydroxide in corrosive/irritant effects.

As discussed previously, this exceedance of the ERPG-3 criterion would not be expected to result in irreversible or life threatening health effects.

For the next nearest noninvolved worker population (1,500 workers at 1,780 m [5,840 ft]), the cumulative acute hazard ratio was 1.20E+00 for ERPG-1, indicating that only mild irreversible irritant effects would be anticipated. For the MEI general public, the cumulative acute hazard ratio was less than 1.0 for all ERPGs and no acute health effects would be expected.

Under bounding conditions, the cumulative acute hazard ratios for the MEI noninvolved worker and nearest noninvolved worker (335 workers at 290 m [950 ft]) were 7.31E+02 and 2.65E+00, respectively, for ERPG-3, indicating the potential for irreversible health effects that could be life threatening. These acute hazard ratios were primarily attributable to:

- Sodium (approximately 83 percent of the total hazard ratio); and
- Calcium (approximately 10 percent of the total hazard ratio).

As discussed previously, this exceedance of the ERPG-3 criterion would not be expected to result in irreversible or life threatening health effects.

For the next nearest noninvolved worker and MEI general public, the cumulative acute hazard ratios were 1.74E+00 and 1.42E+00, respectively, for ERPG-1, indicating that only mild, transient irritant effects would be expected.

Under both nominal and bounding conditions, the probability of a seismic event is 3.64E-03.

E.9.3. 8 Occupation Injuries, Illnesses, and Fatalities from Operations

The number of operation personnel to support the Ex Situ/In Situ Combination 1 alternative was estimated at an average of 5.25E+04 person-years (Jacobs 1996).

The total recordable injuries and illnesses, lost workday cases, and fatalities were calculated as follows:

Total Recordable Cases = (5.25E +04 person-years) · (2.2E+00 incidences/100 person-years) = 1.16E+03

Lost Workday Cases = (5.25E +04 person-years) · (1.1E+00 incidences/100 person-years) = 5.78E+02

Fatalities = (5.25E +04 person-years) · (3.20E-03 fatalities/100 person-years) = 1.68E+00

E.9.4 POST-REMEDIATION ACCIDENT

E.9.4.1 Deflagration in Storage Tank

The tanks that have had 99 percent of their waste removed and filled with gravel do not pose a credible risk. However, the tanks that have been saltwell pumped and filled with gravel may. After the tanks have been filled with gravel, the dome sealed off, and the Hanford Barrier placed over the tank farms, it was postulated that hydrogen builds up in the tank, reaches the LFL, and ignites. The probable sequence of events is that the tank would breach and possibly the asphalt layer in the Hanford Barrier would crack allowing an increased movement of the residual tank waste into the groundwater. An explosion that could breach the dome, displace 2 m (7 ft) of overburden, and displace an additional 5 m (15 ft) of the Hanford Barrier, is considered to be incredible.

For this event to occur, the following conditions must exist:

- Flammable gases must be generated from the waste;
- The concentration of the flammable gas must exceed the lower flammability limit;
- There must be an ignition source; and
- The deflagration would have to generate enough energy to breach the tank and crack the asphalt liner.

Generation of Flammable Gas

All 177 waste tanks produce flammable gases at the molecular level such as hydrogen, ammonia, and methane due to radiolysis, organic degradation, and corrosion.

Gas Concentration

Gases generated from the residual tank waste would diffuse and accumulate in the voids within the gravel and the tank headspace created by the waste settling under the pressure of the fill. If the hydrogen is not allowed to escape from the tank through leaks or cracks in the tank, the hydrogen concentration will continue to increase as long as the potential for radiolysis, organic degradation, or corrosion exists.

It has been shown in tank waste that hydrogen generation rates may drop by approximately one-half every 15 years. Therefore, the gas concentration potential could be reduced by allowing the tanks to vent for 100 years (during institutional controls) through vent pipes passing up through the Hanford Barrier. The vents could then be sealed off. Allowing the tanks to vent for 100 years would reduce the probability of hydrogen reaching the LFL in the tank. Hydrogen gas concentration could be retarded by placing catalytic recombiners in the tank that would recombine hydrogen and oxygen.

Ignition of Gas

If the gas concentrations in the tank manage to exceed the LFL, the ignition sources are limited. Possible ignition sources would include a lightning strike, an earthquake, or heat produced by reactions taking place in the materials remaining in the tank. If the gas was ignited, the propagation of the burn through the gravel is dependent upon the size of the voids in the gravel matrix. Flames will not propagate in a porous material if the pore size is less than a critical value.

Consequences

The probable sequence of events is that the tank would breach and possibly the asphalt layer in the Hanford Barrier would crack allowing an increased movement of the residual tank waste into the groundwater.

E.9.4.2 Seismic Induced Rupture of Stabilized Tanks

As discussed in Section E.4.4.2, displacement on a fault that would increase exposure to the waste after remediation is considered to be incredible. The tanks would most likely crack, allowing increased infiltration to the groundwater.

E.9.5 SUMMARY OF ACCIDENTS

The potential consequences from nonradiological and nonchemical accidents that include occupational and transportation impacts are summarized in Table E.9.5.1. The LCFs associated with representative accidents for each component of the alternative are summarized in Table E.9.5.2 along with the probability of the accident. The chemical hazards associated with representative accidents for each component of the alternative are summarized in Table E.9.5.3. The chemical hazard is expressed as an exceedance of the ERPG threshold values.

Table E.9.5.1 Summary of Potential Nonradiological/Nonchemical Accident Consequences

Table E.9.5.2 Summary of Potential Radiological Accident Consequences

Table E.9.5.3 Chemical Exposures Resulting from Potential Operations and Transportation Accidents

E.10.0 EX SITU/IN SITU COMBINATION 2 ALTERNATIVE

The Ex Situ/In Situ Combination 2 alternative is a combination of the Ex Situ Intermediate Separations alternative and the In Situ Fill and Cap alternative. The Ex Situ/In Situ Combination 2 alternative would involve ex situ treatment and disposal of some waste and in situ treatment of the remaining waste like Ex Situ/In Situ Combination 1, except that there would be retrieval from fewer tanks. This section analyzes and compares the construction, operation, and transportation risks associated with this alternative.

E.10.1 CONSTRUCTION ACCIDENTS

The construction activities associated with the Ex Situ/In Situ Combination 2 alternative are discussed in Appendix B of the EIS. It should be noted there are no radiological or chemical consequences associated with construction accidents. Occupational injuries, illnesses, and fatalities resulting from potential construction accidents are calculated as follows.

The number of construction personnel to support the Ex Situ/In Situ Combination 2 alternative was estimated at an average of 1.79E+04 person-years (Jacobs 1996).

The following total recordable injuries and illnesses, lost workday cases, and fatalities were calculated using the incidence rates from Table E.1.2.1:

Total Recordable Cases = (1.79E+04 person-years) · (9.75E+00 incidences/100 person-years) = 1.74E+03

Lost Workday Cases = (1.79E+04 person-years) · (2.45E+00 incidences/100 person-years) = 4.38E+02

Fatalities = (1.79E+04 person-years) · (3.20E-03 fatalities/100 person-years) =5.72E-01

E.10.2 TRANSPORTATION ACCIDENTS

Transportation activities associated with this alternative are:

- Transporting residual SST waste to vitrification facility;
- Transporting earthen material from onsite borrow sites to fill tank voids;
- Transporting earthen material from onsite borrow sites for Hanford Barrier;
- Transporting construction material to the Hanford Site; and
- Employees commuting to work each day.

E.10.2.1 Radiological Consequences

The methodology for determining radiological consequences from accidents while transporting residual SST waste to the vitrification facility was previously discussed in Section E.6.2.1.

The receptor dose and LCF risk resulting from the accident analysis for retrieval of SST residuals is presented in Table E.10.2.1 for the integrated population and Table E.10.2.2 for the MEI worker and MEI general public.

Table E.10.2.1 Integrated Radiological Impact from Retrieval Transport Accidents

Table E.10.2.2 Maximally-Exposed Individual Radiological Impact from Retrieval Transport Accidents

There would be no LCFs resulting from an accident while transporting retrieved waste onsite.

E.10.2.2 Chemical Exposure

The same chemicals would be transported to the Hanford Site by truck and rail as in the Ex Situ Intermediate Separations alternative. Therefore, the chemical exposure resulting from an accident would be the same as that shown in Table E.6.2.4 for Ex Situ Intermediate Separations alternative.

However, there would be 70 percent fewer shipments, which equates to a 70 percent reduction in the probability of an accident.

The general public exposure to anhydrous ammonia would exceed the ratio of exposure to ERPG-3 by 1.24E+01 and sodium hydroxide would exceed the ratio of exposure to ERPG-1 by 2.45E+00 for corrosive/irritant chemicals. Consequently, this exposure to the MEI general public could potentially result in lethal effects.

E.10.2.3 Occupational Injuries and Fatalities

Truck and Rail Transportation

Injuries and fatalities resulting from direct impact of transportation accidents are analyzed in this subsection. Rail and truck transportation activities to transport material and supplies to the Site for this alternative represents 70 percent of retrieval, 70 percent of vitrification plant construction, and 60 percent of vitrification operations of the data values in the Ex Situ/In Situ Combination 1 alternative. Closure represents 16 percent of the closure data values in the extensive retrieval engineering data package (WHC 1995j) plus 84 percent of the closure data values for In Situ Fill and Cap in the in situ vitrification engineering data package (WHC 1995f). The results are summarized in Table E.10.2.3.

Table E.10.2.3 Summary of Transportation Activities for the Ex Situ/In Situ Combination 2 Alternative

The number of injuries and fatalities were calculated by multiplying the total distance traveled in each zone shown in Table E.10.2.4 by the appropriate unit risk factors shown in Table E.1.3.1. The distance traveled in the population zones were calculated using the methodology previously discussed in Section E.1.3.

Table E.10.2.4 Distance Traveled in Population Zones for the Ex Situ/In Situ Combination 2 Alternative

The expected injuries and fatalities resulting from transportation accidents associated with the ExSitu/In Situ Combination 2 alternative are summarized in Table E.10.2.5.

Table E.10.2.5 Fatalities and Injuries Resulting from Truck and Rail Transportation Accidents for the Ex Situ/In Situ Combination 2 Alternative

Employee Traffic

In addition to transporting materials and supplies to and from the Hanford Site by truck and rail, Site workers and other personnel required to perform the various activities would be driving to the Site in their vehicles. The total person-years to perform the activities was estimated at 5.36+04 (Jacobs 1996).

Each person was assumed to work 260 days of the year. The round-trip distance traveled to work from the Tri-Cities area was estimated at 140 km (87 mi) with an estimated 1.35 passengers per vehicle (DOE 1994a). From the information listed previously the total employee vehicle distance was calculated as follows:

$$(5.36\text{E+04 person-years}) \cdot (260 \text{ days/year}) \cdot (140 \text{ km/day}) \cdot (1/1.35 \text{ passengers per vehicle}) = 1.45\text{E+09 km } (9.02\text{E+8 mi})$$

To calculate the expected number of injuries and fatalities resulting from vehicle accidents, the injury/fatality rates discussed in Section E.1.3 were used. The expected number of injuries and fatalities resulting from employee vehicle accidents were calculated as follows:

Injuries = (1.45E+09 km) · (7.1E-07 injuries/km) = 1.03E+03

Fatalities = (1.45E+09 km) · (8.98E-09 fatalities/km) =1.30E+01

Cumulative Transportation Injuries and Fatalities

The cumulative nonradiological and nontoxicological injuries and fatalities incurred as a direct result of traffic accident impacts are the sum of the truck and rail transport and employee vehicle accidents. The results are summarized in Table E.10.2.6.

Table E.10.2.6 Cumulative Injuries and Fatalities from Traffic Impacts for the Ex Situ/In Situ Combination 2 Alternative

E.10.3 OPERATION ACCIDENTS

The radiological and chemical operation accidents for the Ex Situ/In Situ Combination 2 alternative are the same as the Ex Situ Intermediate Separations alternative and the In Situ Fill and Cap alternative. The radiological cancer risk and the chemical exposure would be bound by the Ex Situ Intermediate Separations alternative presented in Section E.6.3 and are summarized as follows.

E.10.3.1 Routine Operation - Mispositioned Jumper Accident - Tank Waste Transfers

The dominant routine operations accident during tank waste transfers is the mispositioned jumper accident previously discussed in the No Action alternative in Section E.2.2.1 and are summarized as follows:

Source-Term - The source-term resulting from a spray release in Section E.2.2.1.1 was calculated to be 52 L (14 gal).

Probability - The frequency of a mispositioned jumper in Section E.2.2.1.2 was 1.1E-02 per year. The Ex Situ/In Situ Combination 2 alternative was based on 16 years of operations; therefore, the probability was calculated to be 1.8E-01.

Radiological Consequences - The radiological consequences presented in Table E.2.2.2 are reproduced in Table E.10.3.1.

Table E.10.3.1 Dose Consequence from Mispositioned Jumper

Radiological Cancer Risk - The LCFs calculated in Section E.2.2.1.4 are the same for the Ex Situ/In Situ Combination 2 alternative; however, the LCF risk (point estimate) is not the same due to the difference in probabilities. The LCFs and the LCF risk are calculated in Table E.10.3.2. The bounding scenario calculations show that all 10 workers would potentially receive a fatal dose and assumably die directly after the exposure if the accident occurred. There would be approximately seven LCFs from the noninvolved worker population and two from the general public. The nominal scenario calculations show there would be no LCFs.

Table E.10.3.2 Latent Cancer Fatality Risk from Mispositioned Jumper

Chemical Consequences

Potential acute hazards associated with a mispositioned jumper are identical to those summarized in Tables E.2.2.4 (toxic chemicals, nominal conditions), E.2.2.5 (toxic chemicals, bounding conditions), E.2.2.6 (corrosive/irritant chemicals, nominal conditions) and E.2.2.7 (corrosive/irritant chemicals, bounding conditions) for the No Action alternative.

Toxic Impact from Chemical Exposure

Under nominal conditions (Table E.2.2.4), the cumulative acute hazard ratios for the MEI worker, MEI noninvolved worker, and MEI general public were less than 1.0, indicating that no adverse acute health effects would be expected for these three receptors. Under bounding conditions (Table E.2.2.5), the MEI worker was not evaluated because death would occur from exposure to radionuclides. The cumulative acute hazard ratio for the MEI noninvolved worker was 5.36E+00 for ERPG-2, indicating that reversible acute health effects would be expected. This acute hazard ratio was primarily attributable to mercury (approximately 89 percent of the overall hazard ratio). No adverse acute health effects were predicted for the MEI general public under bounding conditions.

Corrosive/Irritant Impact from Chemical Exposure

Under nominal conditions (Table E.2.2.6), the cumulative acute hazard ratio for the MEI worker was 2.70E+00 for ERPG-3, indicating the potential for irreversible health effects that could be life threatening. This acute hazard ratio was almost entirely attributable to sodium assumed to be equivalent to sodium hydroxide in corrosive/irritant effects. For the MEI noninvolved worker, the cumulative acute hazard ratio for ERPG-1 was 3.00E+00, indicating that only mild reversible irritant effects would be expected. No acute health impacts were predicted for the MEI general public under nominal conditions. Under bounding conditions (Table E.2.2.7), the MEI worker was not evaluated because death would occur from exposure to radionuclides. For the MEI noninvolved worker, the cumulative acute hazard ratio for ERPG-1 was 4.36E+00, indicating that only mild, reversible irritant effects would be expected. No acute health impacts were predicted for the MEI general public under bounding conditions.

Under both nominal and bounding conditions, the probability of a mispositioned jumper is 1.75E-01.

E.10.3.2 Continued Operations Accident - Waste Storage Tanks

The dominant accident is a hydrogen deflagration in a waste storage tank previously discussed in the No Action alternative in Section E.2.2.2.1 and is summarized as follows:

Source-Term - The source-term resulting from the fire in Section E.2.2.2.1 was calculated to be 2.4 L (0.6 gal).

Probability - The frequency of the hydrogen deflagration in a waste storage tank in Section E.2.2.2.2 was estimated to be 7.2E-03 per year. The probability of the scenario based on 25 years of operation was therefore estimated to be 1.8E01.

Radiological Consequences - The radiological consequences presented in Table E.2.2.8 are reproduced in Table E.10.3.3.

Table E.10.3.3 Dose Consequence from Hydrogen Deflagration in Waste Storage Tank

Radiological Cancer Risk - The LCFs calculated in Section E.2.2.2.4 are reproduced in Table E.10.3.4.

Table E.10.3.4 Latent Cancer Fatality Risk from Hydrogen Deflagration in Waste Storage Tank

In the bounding scenario all 10 workers would potentially receive a fatal dose and assumably die directly after the exposure. There would also be 10 LCFs attributed to the exposure to the noninvolved workers and 2 LCFs to the general public if the accident occurred. The nominal scenario calculations show there would be no LCFs.

Chemical Consequences

Potential acute hazards associated with a hydrogen burn in a waste storage tank are identical to those summarized in Tables E.2.2.10 (toxic chemicals, nominal conditions), E.2.2.11 (toxic chemicals, bounding conditions), E.2.2.12 (corrosive/irritant chemicals, nominal conditions) and E.2.2.13 (corrosive/irritant chemicals, bounding conditions) for the No Action alternative.

Under bounding conditions, chemical impacts were not evaluated for the MEI worker because all workers would receive a lethal radiation dose, as discussed previously.

Toxic Impact from Chemical Exposure

Under nominal conditions (Table E.2.2.10), the cumulative acute hazard ratio for the MEI worker was 1.57E+00 for ERPG-2, indicating that reversible acute health effects would be expected. This acute hazard ratio was primarily attributable to TOC (approximately 87 percent of the overall ERPG-2 ratio). The TOC is assumed to be equivalent in toxicity to tributylphosphate, which is the most acutely toxic constituent of the organic analytes identified. Tributylphosphate was used as a surrogate because an inventory of the various chemicals that make up the TOC class is not available. For the MEI noninvolved worker, the cumulative acute hazard ratio for ERPG-3 was 9.38E+00, indicating the potential for irreversible health effects that could be life threatening. This acute hazard ratio was also primarily attributable to TOC (approximately 90 percent of the overall ERPG-3 ratio). However, the MEI noninvolved worker is a hypothetical worker assumed to be located 100 m (330 ft) from the source area. The nearest noninvolved worker population is located 290 m (950 ft) from the source area and had no cumulative acute hazard ratios greater than 1.0 for any of the ERPGs, indicating that no acute health effects would be expected for the nearest noninvolved worker population. Likewise, no acute health effects were predicted for the MEI general public under nominal conditions.

Under bounding conditions (Table E.2.2.11), the cumulative acute hazard ratio for the MEI noninvolved worker was 4.54E+02 for ERPG-3, indicating the potential for irreversible health effects that could be life-threatening. This acute hazard ratio is primarily attributable to:

- Oxalate (approximately 37 percent of the total hazard ratio);
- Beryllium (approximately 13 percent of the total hazard ratio);
- Cadmium (approximately 14 percent of the total hazard ratio);
- Uranium (approximately 12 percent of the total hazard ratio); and
- TOC (approximately 8 percent of the total hazard ratio).

As discussed previously, this is a hypothetical receptor located 100 m (330 ft) from the source. The cumulative acute hazard ratio for the nearest noninvolved worker population located 290 m (950 ft) from the source was 1.65E+00 for ERPG-3, indicating the potential for irreversible health effects that could be life threatening for 335 workers. This hazard ratio was attributable to the same toxic chemicals listed above. This exceedance of the ERPG-3 criterion for the nearest noninvolved worker population would not be expected to result in irreversible health effects or place these workers in a life-threatening situation for the following reasons.

- ERPG-3 is defined as a concentration in which a receptor can be exposed for 1 hour without irreversible health effects. Because the Hanford Site has an in-place emergency response plan designed to evacuate workers within 1 hour of an accident, workers would be expected to evacuate their location and move to an area where potential exposures would be well below ERPG-3. Therefore, this worker population would not be exposed to airborne concentrations that would be either life threatening or result in irreversible health effects.
- The estimated air concentrations of chemicals as a result of this accident were based on very conservative meteorology, which results in movement of a plume directly toward the worker population at a relatively slow rate with minimal wind dispersion. If less conservative meteorological parameters were used, wind dispersion would cause the estimated air concentrations of chemicals to be substantially less, and the ERPG-3 criterion would not be exceeded.
- Only the bounding toxic chemical evaluation exceeded ERPG-3, while the nominal evaluation was well below 1.00E+00 for ERPG-3, suggesting that the noninvolved worker population would not receive an exposure that would result in any permanent health effects.

The next nearest noninvolved worker population is located 1,780 m (5,840 ft) from the source and contains 1,500 workers. The cumulative acute hazard ratio was less than 1.0 for all ERPGs, indicating that no acute health effects would be expected for this population of workers. No acute health impacts were predicted for the MEI general public.

Corrosive/Irritant Impact from Chemical Exposure

Under nominal conditions (Table E.2.2.12), the cumulative acute hazard ratio for the MEI worker was 3.82E+00 for ERPG-3, indicating the potential for irreversible corrosive/irritant effects that could be life threatening. For the MEI noninvolved worker, the cumulative acute hazard ratio for ERPG-3 was 7.89E+01 and would indicate irreversible corrosive/irritant effects that could be life threatening for this hypothetical receptor. This hazard ratio was primarily attributable to sodium, which was assumed to be equivalent to sodium hydroxide in corrosive/irritant effects. For the nearest noninvolved worker population (290 m [950 ft]) composed of 335 workers, the cumulative acute hazard ratio for ERPG-1 was 1.38E+01, indicating that only mild, reversible effects would be expected. No acute health impacts were predicted for the MEI general public under nominal conditions.

Under bounding conditions (Table E.2.2.13), the cumulative acute hazard ratio for the MEI noninvolved worker was 1.91E+02 for ERPG-3, indicating irreversible health effects that could be life threatening for this hypothetical receptor. This hazard ratio was primarily attributable to:

- Sodium as sodium hydroxide (approximately 75 percent of the total hazard ratio);
- Chromium (approximately 14 percent of the total hazard ratio); and
- Calcium (approximately 6 percent of the total hazard ratio).

For the nearest noninvolved worker population (290 m [950 ft]) composed of 335 workers, the cumulative acute hazard ratio was 1.74E+00 for ERPG-2, indicating that reversible acute effects would be expected. No acute health impacts were predicted for the MEI general public under nominal conditions.

Under both nominal and bounding conditions, the probability of a hydrogen deflagration event in a waste storage tank is 1.80E-01.

E.10.3.3 Retrieval - Loss of Filtration Accident

The dominant retrieval operations accident is the loss of filtration accident previously discussed in the Ex Situ Intermediate Separations alternative in Section E.6.3.3 and is summarized as follows.

Source-Term - The source-term resulting from the airborne release in Section E.6.3.3.1 was calculated to be 2.5E-01 L (6.6E-02 gal).

Probability - The frequency of a loss of filtration in section E.6.3.3.2 was 8.8E-06 per year. The Ex Situ/In Situ Combination 2 retrieval activity was based on 25 years of operations; therefore, the probability was calculated to be 2.2E-04.

Radiological Consequences - The radiological consequences presented in Section 6.3.3.3 are reproduced in Table E.10.3.5.

Table E.10.3.5 Dose Consequence from Loss of Filtration

Radiological Cancer Risk - The LCFs and the LCF point estimate risk were calculated for the receptors and are presented in Table E.10.3.6.

Table E.10.3.6 Latent Cancer Fatality Risk from Loss of Filtration

In the bounding scenario all 10 workers would potentially receive a fatal dose and assumably die directly after the exposure if the accident occurred. The calculations also show there would be less than one LCF attributed to the exposure to the noninvolved workers and the general public if the accident occurred. The nominal scenario calculations show there would be no LCFs.

Chemical Consequences

The chemical exposure to the receptors from the postulated accident was calculated in Appendix A of the accident data package (Shire et al. 1995 and Jacobs 1996) and summarized in the exposure column in Tables E.6.3.8 and E.6.3.9 for the nominal and bounding toxic effects, respectively, and Tables E.6.3.10 and E.6.3.11 for the nominal and bounding corrosive/irritant effects, respectively. The tables compare the concentration of postulated chemical releases to acute exposure criteria (ERPGs) discussed in Section 1.1.7.

Under bounding conditions, chemical impacts were not evaluated for the MEI worker because all workers would receive a lethal radiation dose, as discussed previously.

Under nominal conditions (Table E.6.3.8), the cumulative acute hazard ratio for the MEI worker was less than 1.0 for all ERPGs, indicating that no adverse acute health effects would be expected. For the MEI noninvolved worker, the cumulative acute hazard ratio was 1.84E+00 for ERPG-1, indicating that only mild, transient, acute health effects would be expected. No acute health effects were predicted for the MEI general public under nominal conditions.

Under bounding conditions (Table E.6.3.9), the cumulative acute hazard ratio for the MEI noninvolved worker was 7.27E+01 for ERPG-3, indicating the potential for irreversible health effects that could be life threatening. This acute hazard ratio is primarily attributable to:

- Uranium (approximately 48 percent of the total hazard ratio);
- Oxalate (approximately 24 percent of the total hazard ratio);
- Mercury (approximately 13 percent of the total hazard ratio); and
- TOC (approximately 7 percent of the total hazard ratio).

As discussed previously, this is a hypothetical receptor located 100 m (330 ft) from the source. The cumulative acute hazard ratio for the nearest noninvolved worker population (335 workers) located 290 m (950 ft) from the source was 5.40E+00 for ERPG-2, indicating that reversible acute health effects would be expected. No acute health impacts were predicted for the MEI general public.

Corrosive/Irritant Impact from Loss of Filtration

Under nominal conditions (Table E.6.3.10), the cumulative acute hazard ratio for the MEI worker was 2.11E+00 for ERPG-2, indicating that reversible corrosive/irritant effects would be expected. For the MEI noninvolved worker, the cumulative acute hazard ratio for ERPG-3 was 1.72E+01 and would indicate irreversible corrosive/irritant effects that could be life threatening for this hypothetical receptor. This hazard ratio was primarily attributable to sodium, which was assumed to be equivalent to sodium hydroxide in corrosive/irritant effects. For the nearest noninvolved worker population (290 m [950 ft]) composed of 335 workers, the cumulative acute hazard ratio for ERPG-1 was 3.02E+00, indicating that only mild, transient irritant effects would be expected. No acute health impacts were predicted for the MEI general public under nominal conditions.

Under bounding conditions (Table E.6.3.11), the cumulative acute hazard ratio for the MEI noninvolved worker was 2.47E+01 for ERPG-3, indicating irreversible health effects that could be life threatening for this hypothetical receptor. This hazard ratio was primarily attributable to :

- Sodium as sodium hydroxide (approximately 82 percent of the total hazard ratio); and
- Calcium (approximately 9 percent of the total hazard ratio).

For the nearest noninvolved worker population (290 m [950 ft]) composed of 335 workers, the cumulative acute hazard ratio was 4.38E+00 for ERPG-1, indicating that only mild, transient irritant effects would be expected. No acute health impacts were predicted for the MEI general public under nominal conditions.

Under both nominal and bounding conditions, the probability of a loss of filtration event in a waste storage tank is 2.20E-04.

E.10.3.4 Pretreatment - Seismic Induced Line Break in Vault

The dominant pretreatment operations accident is the seismic-induced line break in vault accident previously discussed in the Ex Situ Intermediate Separations alternative in Section E.6.3.4 and is summarized as follows:

Source-Term - The source-term resulting from the airborne release in Section E.6.3.4.1 was calculated to be 7.3E-02

L (1.9E-02 gal).

Probability - The annual exceedance frequency of the seismic event in Section E.6.3.4.2 was 6.5E-04 per year. The Ex Situ/In Situ Combination 2 alternative was based on 25 years of operations; therefore, the probability was calculated to be 1.6E-02.

Radiological Consequences - The radiological consequences presented in Section 6.3.4.3 are reproduced in Table E.10.3.7.

Table E.10.3.7 Dose Consequence from Seismic Induced Line Break in Vault

Radiological Cancer Risk - The LCFs and the LCF point estimate risk were calculated for the receptors and presented in Table E.10.3.8. The calculations show there would be no LCFs attributable to this exposure if the accident occurs for the bounding and nominal scenarios.

Table E.10.3.8 Latent Cancer Fatality Risk from Seismic-Induced Line Break in Vault

Chemical Consequences

The chemical exposure to the receptors from the postulated accident was calculated in Appendix A of the accident data package (Shire et al. 1995 and Jacobs 1996) and summarized in the exposure column in Tables E.6.3.14 and E.6.3.15 for the nominal and bounding toxic effects, respectively, and Tables E.6.3.16 and E.6.3.17 for the nominal and bounding corrosive/irritant effects, respectively. The tables compare the concentration of postulated chemical releases to acute exposure criteria (ERPGs) discussed in Section 1.1.7.

Toxic Impact from Chemical Exposure

Under nominal conditions (Table E.6.3.14), the cumulative acute hazard ratios for the MEI worker, MEI noninvolved worker, and MEI general public were less than 1.0, indicating that no adverse acute health effects would be expected for these three receptors. Under bounding conditions (Table E.6.3.15), the cumulative acute hazard ratios for the MEI worker, MEI noninvolved worker and MEI general public were less than 1.0, indicating that no adverse acute health effects would be expected for these three receptors.

Corrosive/Irritant Impact from Chemical Exposure

Under nominal conditions (Table E.6.3.16), the cumulative acute hazard ratios for the MEI worker, MEI noninvolved worker, and MEI general public were less than 1.0, indicating that no adverse acute health effects would be expected for these three receptors. Under bounding conditions (Table E.6.3.17), the cumulative acute hazard ratios for the MEI worker, MEI noninvolved worker, and MEI general public were less than 1.0, indicating that no adverse acute health effects would be expected for these three receptors.

Under both nominal and bounding conditions, the probability of a pretreatment spray release is 1.63E-02 .

E.10.3.5 Treatment (Ex Situ Vitrification) - Canister of Vitrified High-Level Waste Inadvertently Drops and Ruptures

The dominant immobilization operations accident is the "canister of vitrified HLW inadvertently drops and ruptures" accident previously discussed in the Ex Situ Intermediate Separations alternative in Section E.6.3.5 and is summarized as follows:

Source-Term - The source-term resulting from the airborne release in Section E.6.3.5.1 was calculated to be 2.5E-06 g (8.8E-08 oz).

Probability - The frequency of the accident in Section E.6.3.5.2 was 6.0E-01 per year. The Ex Situ/In Situ Combination 2 alternative was based on 25 years of operations; therefore, the probability was calculated to be 1.0E+00.

Radiological Consequences - The radiological consequences presented in Section 6.3.5.3 are reproduced in Table E.10.3.9.

Table E.10.3.9 Dose Consequence from Breached Canister

Radiological Cancer Risk - The LCFs and the LCF point estimate risk were calculated for the receptors and presented in Table E.10.3.10. The calculations show there would be no LCFs attributable to this exposure if the accident occurs for the bounding and nominal scenarios.

Table E.10.3.10 Latent Cancer Fatality Risk from Breached Canister

Chemical Consequences - No chemical consequences were evaluated (Shire et al. 1995 and Jacobs 1996) because the release would be through two-stage HEPA filters that would reduce the source-term well below the cumulative ratio of exposure to ERPG-1 values for toxic or corrosive/irritant chemicals.

E.10.3.6 Treatment - In Situ Fill and Cap

The dominant treatment operations accident is the tank deflagration accident resulting in a tank dome collapse previously discussed in the In Situ Fill and Cap alternative in Section E.4.3.3 and is summarized as follows:

Source-Term - The source-term resulting from the airborne release in Section E.4.3.3.1 was calculated to be 7.5 L (2.0 gal).

Probability - The probability of a tank dome collapse in Section E.4.3.3.2 was assumed to be 1.0E-04.

Radiological Consequences - The radiological consequences presented in Section 4.3.3.3 are reproduced in Table E.10.3.11.

Table E.10.3.11 Dose Consequence from Tank Dome Collapse Due to Deflagration

Radiological Cancer Risk - All 10 workers and the MEI noninvolved worker would potentially receive a lethal dose. The LCFs and the LCF point estimate risk were calculated for the receptors and presented in Table E.10.3.12.

Table E.10.3.12 Latent Cancer Fatality Risk from Tank Dome Collapse Due to Deflagration

In addition to all 10 workers dying from a lethal dose, the calculations show there would be eleven LCFs attributed to the exposure to the noninvolved workers and two LCFs attributed to the general public if the accident occurred. The nominal scenario calculations show there would be no LCFs.

E.10.3.6.1 Chemical Consequences of Tank Dome Collapse

The chemical exposure to the receptors from the postulated accident was identical to that summarized in the exposure column in Tables E.4.3.8 and E.4.3.9 for the nominal and bounding toxic effects, respectively, and Tables E.4.3.10 and E.4.3.11 for the nominal and bounding corrosive/irritant effects, respectively. The tables compare the concentration of postulated chemical releases to acute exposure criteria (ERPGs) discussed in Section 1.1.7.

Under bounding conditions, chemical impacts were not evaluated for the MEI worker because all workers would receive a lethal radiation dose, as discussed previously.

Toxic Impact from Chemical Exposure

Under nominal conditions (Table E.4.3.8), the cumulative acute hazard ratio for the MEI worker was 2.64E+00 for ERPG-1, indicating that only mild transient effects would be expected. For the MEI noninvolved worker, the cumulative acute health hazard was 2.59E+00 for ERPG-3, indicating the potential for irreversible health effects that could be life threatening. This acute hazard ratio was primarily attributable to TOC (approximately 84 percent of the total hazard ratio). The TOC is assumed to be equivalent in toxicity to tributylphosphate, which is the most acutely toxic constituent of the organic analytes identified. Tributylphosphate was used as a surrogate because an inventory of the various chemicals that make up the TOC class is not available. The cumulative acute hazard ratio for the nearest noninvolved worker population (consisting of 335 workers located 290 m [950 ft] away) was less than 1.0 for all ERPGs, suggesting that no acute health effects would be expected.

Under bounding conditions (Table E.4.3.9), the cumulative hazard ratios for the MEI and nearest noninvolved worker (335 workers located 290 m [950 ft] away) were 2.15E+03 and 7.80E+00 for ERPG-3, respectively. These ratios were primarily attributable to:

- Uranium (approximately 47 percent of the total hazard ratio);
- Oxalate (approximately 24 percent of the total hazard ratio); and
- Mercury (approximately 13 percent of the total hazard ratio).

This exceedance of the ERPG-3 criterion for the nearest noninvolved worker population would not be expected to result in irreversible health effects or place these workers in a life-threatening situation for the following reasons.

- ERPG-3 is defined as a concentration in which a receptor can be exposed for 1 hour without irreversible health effects. Because the Hanford Site has an in-place emergency response plan designed to evacuate workers within 1 hour of an accident, workers would be expected to evacuate their location and move to an area where potential exposures would be well below ERPG-3. Therefore, this worker population would not be exposed to airborne concentrations that would be either life threatening or result in irreversible health effects.
- The estimated air concentrations of chemicals as a result of this accident were based on very conservative meteorology, which results in movement of a plume directly toward the worker population at a relatively slow rate with minimal wind dispersion. If less conservative meteorological parameters were used, wind dispersion would cause the estimated air concentrations of chemicals to be substantially less, and the ERPG-3 criterion would not be exceeded.
- Only the bounding toxic chemical evaluation exceeded ERPG-3, while the nominal evaluation was well below 1.00E+00 for ERPG-3, suggesting that the noninvolved worker population would not receive an exposure that would result in any permanent health effects.

The cumulative acute hazard ratio for the next nearest noninvolved worker population, composed of 1,500 people and located 1,780 m (5,840 ft) away, was 2.15E+00 for ERPG-2, indicating that reversible acute health effects would be expected. The cumulative acute hazard ratio for the MEI general public was 1.76E+00 for ERPG-2, indicating that reversible acute health effects would be expected.

Corrosive/Irritant Impact from Chemical Exposure

Under nominal conditions (Table E.4.3.10), the cumulative acute hazard ratios for the MEI worker, MEI noninvolved worker, and nearest noninvolved worker (335 workers at 290 m [950 ft]) were 2.47E+01, 5.10E+02 and 1.85E+00, respectively, for ERPG-3, indicating the potential for irreversible health effects that could be life threatening. These ratios were almost entirely attributable to sodium, which was assumed to be equivalent to sodium hydroxide in corrosive/irritant effects.

As discussed previously, this exceedance of the ERPG-3 criterion would not be expected to result in irreversible or life threatening health effects.

For the next nearest noninvolved worker population (1,500 workers at 1,780 m [5,840 ft]), the cumulative acute hazard ratio was 1.20E+00 for ERPG-1, indicating that only mild irreversible irritant effects would be anticipated. For the MEI general public, the cumulative acute hazard ratio was less than 1.0 for all ERPGs, and no acute health effects would be expected.

Under bounding conditions (Table E.4.3.11), the cumulative acute hazard ratios for the MEI noninvolved worker and nearest noninvolved worker (335 workers at 290 m [950 ft]) were 7.31E+02 and 2.65E+00, respectively for ERPG-3, indicating the potential for irreversible health effects that could be life threatening. These acute hazard ratios were primarily attributable to:

- Sodium (approximately 83 percent of the total hazard ratio); and
- Calcium (approximately 10 percent of the total hazard ratio).

As discussed previously, this exceedance of the ERPG-3 criterion would not be expected to result in irreversible or life threatening health effects.

For the next nearest noninvolved worker and MEI general public, the cumulative acute hazard ratios were 1.74E+00 and 1.42E+00, respectively for ERPG-1, indicating that only mild, transient irritant effects would be expected.

Under both nominal and bounding conditions, the probability of a seismic event is 1.00E-04.

E.10.3.7 Beyond Design Basis Accident

The beyond design basis accident is a seismic event resulting in the collapse of a SST. In the event of a 0.43 g earthquake, a SST could potentially collapse (LANL 1995). This event is not dependent on the remediation alternative but has the same annual frequency regardless of the alternative that is chosen. The length of time unremediated waste would remain in tanks that have not been backfilled would vary depending on the alternative and would affect the probability of the event. The probability of the event is the product of the annual frequency of the earthquake and the number of years the waste remains untreated in the unstabilized tanks.

At smaller annual frequencies, larger earthquakes could occur resulting in greater destruction and larger numbers of LCF to the onsite and offsite populations. In addition to population exposures from the collapsed SSTs, the impact to other Hanford Site facilities and operations would potentially add to the chemical and radiological risk. This would be a severe earthquake that would cause catastrophic structural damage in the Tri-Cities and the Hanford Site with expected extensive loss of life. There would be injuries and fatalities resulting from collapsed buildings and homes, fires, and traffic accidents. However, this section evaluates the radiological and chemical impacts resulting from the collapse of one SST.

E.10.3.7.1 Source-Term Development

It was conservatively assumed that the radiological and chemical contaminants in the headspace are available for release. The collapse of a portion of the dome and overburden compresses the vapor in the headspace as it descends, enhancing the vapor release rate by a sudden pressure difference. Assuming for each tank a respirable concentration of contaminants in the headspace of 100 mg/m^3, a liquid SpG of 1.5, and a headspace volume of 1,000 m^3 (Shire et al. 1995 and Jacobs 1996), the potential source-term contribution from the headspace release was calculated as follows:

$$(100\ \text{mg/m}^3) \cdot (1\ \text{g}/1{,}000\ \text{mg}) \cdot (1\ \text{L}/1{,}000\ \text{g}) \cdot (1{,}000\ \text{m}^3) \cdot (1/1.5) = 6.67\text{E-}02\ \text{L}\ (1.8\text{E-}02\ \text{gal}).$$

It was conservatively assumed that the liquids had been pumped from the tanks so that the tanks contained only solids and the MAR was 2,500 L (660 gal) for each tank. It was postulated that the fall of the dome and overburden generated an air movement sufficient to suspend a fraction the MAR. Assuming the respirable release fraction to be 2.0E-03 (Shire et al. 1995 and Jacobs 1996), the potential source-term contribution was calculated as follows:

$$(2{,}500\ \text{L}) \cdot (2.0\text{E-}03) = 5.0\ \text{L}\ (1.3\ \text{gal}).$$

It was postulated that prevailing winds resuspend a respirable fraction of the MAR (2,500 L [660 gal]). A respirable release fraction of 4.0E-05/hr for 24 hours was assumed. The potential source-term contribution from resuspension was calculated as follows:

$$(2{,}500\ \text{L}) \cdot (4.0\text{E-}05/\text{hr}) \cdot (24\ \text{hr}) = 2.4\ \text{L}\ (0.6\ \text{gal}).$$

The combined source-term for the acute release is calculated as follows:

(6.67E-02 L) + (5.0 L) + (2.4 L) = 7.4 L (2.0 gal).

E.10.3.7.2 Probability of a Beyond Design Basis Earthquake

This earthquake has a calculated annual exceedance frequency of approximately 1.40E-04 (WHC 1996b). The probability for this scenario based on 25 years of operation was therefore estimated to be 3.5E-03.

E.10.3.7.3 Radiological Consequences from a Beyond Design Basis Earthquake

The radiological dose to the receptors from the previous source-term was calculated by the GENII computer code (Napier et al. 1988) using the methodology previously discussed in Section E.1.1.6. The results are presented in Table E.10.3.13.

Table E.10.3.13 Dose Consequence from Seismic Event

E.10.3.7.4 Radiological Cancer Risk from a Beyond Design Basis Earthquake

The LCFs and LCF point estimate risk are presented in Table E.10.3.14.

Table E.10.3.14 Latent Cancer Fatality Risk from Seismic Event

In the bounding scenario, all 10 workers would potentially receive a fatal dose and assumably die directly after the exposure. There would also be 10 LCFs attributed to the exposure to the noninvolved workers and two LCFs to the general public if the accident occurred. The nominal scenario calculations show there would be no LCFs.

E.10.3.7.5 Chemical Consequences from a Beyond Design Basis Earthquake

Potential acute hazards associated with a beyond design basis earthquake are identical to those summarized in Tables E.2.2.16 (toxic chemicals, nominal conditions), E.2.2.17 (toxic chemicals, bounding conditions), E.2.2.18 (corrosive/irritant chemicals, nominal conditions) and E.2.2.18 (corrosive/irritant chemicals, bounding conditions) for the No Action alternative.

Under bounding conditions, chemical impacts were not evaluated for the MEI worker because all workers would receive a lethal radiation dose, as described previously.

Toxic Impact from Chemical Exposure

Under nominal conditions, the cumulative acute hazard ratio for the MEI worker was 2.64E+00 for ERPG-1, indicating that only mild transient effects would be expected. For the MEI noninvolved worker, the cumulative acute health hazard was 2.59E+00 for ERPG-3, indicating the potential for irreversible health effects that could be life threatening. This acute hazard ratio was primarily attributable to TOC (approximately 84 percent of the total hazard ratio). The TOC is assumed to be equivalent in toxicity to tributylphosphate, which is the most acutely toxic constituent of the organic analytes identified. Tributylphosphate was used as a surrogate because an inventory of the various chemicals that make up the TOC class is not available. The cumulative acute hazard ratio for the nearest noninvolved worker population (consisting of 335 workers located 290 m [950 ft] away) was less than 1.0 for all ERPGs, suggesting that no acute health effects would be expected.

Under bounding conditions (Table E.2.2.17), the cumulative hazard ratios for the MEI and nearest noninvolved worker (335 workers located 290 m away) were 2.15E+03 and 7.80 for ERPG-3, respectively. These ratios were primarily attributable to:

- Uranium (approximately 47 percent of the total hazard ratio);
- Oxalate (approximately 24 percent of the total hazard ratio); and
- Mercury (approximately 13 percent of the total hazard ratio).

This exceedance of the ERPG-3 criterion for the nearest noninvolved worker population would not be expected to result in irreversible health effects or place these workers in a life-threatening situation for the following reasons.

- ERPG-3 is defined as a concentration in which a receptor can be exposed for 1 hour without irreversible health effects. Because the Hanford Site has an in-place emergency response plan designed to evacuate workers within 1 hour of an accident, workers would be expected to evacuate their location and move to an area where potential exposures would be well below ERPG-3. Therefore, this worker population would not be exposed to airborne concentrations that would be either life threatening or result in irreversible health effects.
- The estimated air concentrations of chemicals as a result of this accident were based on very conservative meteorology, which results in movement of a plume directly toward the worker population at a relatively slow rate with minimal wind dispersion. If less conservative meteorological parameters were used, wind dispersion would cause the estimated air concentrations of chemicals to be substantially less, and the ERPG-3 criterion would not be exceeded.
- Only the bounding toxic chemical evaluation exceeded ERPG-3, while the nominal evaluation was well below 1.00E+00 for ERPG-3, suggesting that the noninvolved worker population would not receive an exposure that would result in any permanent health effects.

The cumulative acute hazard ratio for the next nearest noninvolved worker population, composed of 1,500 people and located 1,780 m (5,840 ft) away, was 2.15E+00 for ERPG-2, indicating that reversible acute health effects would be expected. The cumulative acute hazard ratio for the MEI general public was 1.76E+00 for ERPG-2, indicating that reversible acute health effects would be expected.

Corrosive/Irritant Impact from Chemical Exposure

Under nominal conditions (Table E.2.2.18), the cumulative acute hazard ratios for the MEI worker, MEI noninvolved worker and nearest noninvolved worker (335 workers at 290 m [950 ft]) were 2.47E+01, 5.10E+02 and 1.85E+00, respectively, for ERPG-3, indicating the potential for irreversible health effects that could be life threatening. These ratios were almost entirely attributable to sodium, which was assumed to be equivalent to sodium hydroxide in corrosive/irritant effects.

As discussed previously, this exceedance of the ERPG-3 criterion would not be expected to result in irreversible or life threatening health effects.

For the next nearest noninvolved worker population (1,500 workers at 1,780 m [5,840 ft]), the cumulative acute hazard ratio was 1.20E+00 for ERPG-1, indicating that only mild irreversible irritant effects would be anticipated. For the MEI general public, the cumulative acute hazard ratio was less than 1.0 for all ERPGs and no acute health effects would be expected.

Under bounding conditions, the cumulative acute hazard ratios for the MEI noninvolved worker, and nearest noninvolved worker (335 workers at 290 m [950 ft]) were 7.31E+02 and 2.65E+00, respectively, for ERPG-3, indicating the potential for irreversible health effects that could be life threatening. These acute hazard ratios were primarily attributable to:

- Sodium (approximately 83 percent of the total hazard ratio); and
- Calcium (approximately 10 percent of the total hazard ratio).

As discussed previously, this exceedance of the ERPG-3 criterion would not be expected to result in irreversible or life threatening health effects.

For the next nearest noninvolved worker and MEI general public, the cumulative acute hazard ratios were 1.74E+00 and 1.42E+00, respectively for ERPG-1, indicating that only mild, transient irritant effects would be expected.

Under both nominal and bounding conditions, the probability of a seismic event is 3.50E-03.

E.10.3.8 Occupation Injuries, Illnesses, and Fatalities from Operations

The number of operation personnel to support the Ex Situ/In Situ Combination 2 alternative was estimated at an average of 3.58E+04 person-years (Jacobs 1996).

The total recordable injuries and illnesses, lost workday cases, and fatalities were calculated as follows:

Total Recordable Cases = (3.58E+04 person-years) · (2.2E+00 incidences/100 person-years) = 7.87E+02

Lost Workday Cases = (3.58E+04 person-years) · (1.1E+00 incidences/100 person-years) = 3.93E+02

Fatalities = (3.58E+04 person-years) · (3.20E-03 fatalities/100 person-years) = 1.14E+00

E.10.4 POST-REMEDIATION ACCIDENT

E.10.4.1 Deflagration in Storage Tank

The tanks that have had 99 percent of their waste removed and filled with gravel do not pose a credible risk. However, the tanks that have been saltwell pumped and filled with gravel may. After the tanks have been filled with gravel, the dome sealed off, and the Hanford Barrier placed over the tank farms, it was postulated that hydrogen builds up in the tank, reaches the LFL, and ignites. The probable sequence of events is that the tank would breach and possibly the asphalt layer in the Hanford Barrier would crack allowing an increased movement of the residual tank waste into the groundwater. An explosion that could breach the dome, displace 2 m (7 ft) of overburden, and displace an additional 5 m (15 ft) of the Hanford Barrier, is considered to be incredible.

For this event to occur, the following conditions must exist:

- Flammable gases must be generated from the waste;
- The concentration of the flammable gas must exceed the lower flammability limit;
- There must be an ignition source; and
- The deflagration would have to generate enough energy to breach the tank and crack the asphalt liner.

Generation of Flammable Gas

All 177 waste tanks produce flammable gases at the molecular level such as hydrogen, ammonia, and methane due to radiolysis, organic degradation, and corrosion.

Gas Concentration

Gases generated from the residual tank waste would diffuse and accumulate in the voids within the gravel and the tank headspace created by the waste settling under the pressure of the fill. If the hydrogen is not allowed to escape from the tank through leaks or cracks in the tank, the hydrogen concentration will continqe to increase as long as the potential for radiolysis, organic degradation, or corrosion exists.

It has been shown in tank waste that hydrogen generation rates may drop by approximately one-half every 15 years. Therefore, the gas concentration potential could be reduced by allowing the tanks to vent for 100 years (during institutional controls) through vent pipes passing up through the Hanford Barrier. The vents could then be sealed off. Allowing the tanks to vent for 100 years would reduce the probability of hydrogen reaching the LFL in the tank. Hydrogen gas concentration could be retarded by placing catalytic recombiners in the tank that would recombine hydrogen and oxygen.

Ignition of Gas

If the gas concentrations in the tank manage to exceed the LFL, the ignition sources are limited. Possible ignition sources would include a lightning strike, an earthquake, or heat produced by reactions taking place in the materials remaining in the tank. If the gas was ignited, the propagation of the burn through the gravel is dependent upon the size of the voids in the gravel matrix. Flames will not propagate in a porous material if the pore size is less than a critical value.

Consequences

The probable sequence of events is that the tank would breach and possibly the asphalt layer in the Hanford Barrier would crack allowing an increased movement of the residual tank waste into the groundwater.

E.10.4.2 Seismic Induced Rupture of Stabilized Tanks

As discussed in Section E.4.4.2, displacement on a fault that would increase exposure to the waste after remediation is considered to be incredible. The tanks would most likely crack, allowing increased infiltration to the groundwater.

E.10.5 SUMMARY OF ACCIDENTS

The potential consequences from nonradiological and nonchemical accidents that include occupational and transportation impacts are summarized in Table E.10.5.1. The LCFs associated with representative accidents for each component of the alternative are summarized in Table E.10.5.2 along with the probability of the accident. The chemical hazards associated with representative accidents for each component of the alternative are summarized in Table E.10.5.3. The chemical hazard is expressed as an exceedance of the ERPG threshold values.

Table E.10.5.1 Summary of Potential Nonradiological/Nonchemical Accident Consequences

Table E.10.5.2 Summary of Potential Radiological Accident Consequences

Table E.10.5.3 Chemical Exposures Resulting from Potential Operations and Transportation Accidents

E.11.0 PHASED IMPLEMENTATION ALTERNATIVE

The Phased Implementation alternative includes remediating the tank waste in a two-phase process. The first phase would be a commercial demonstration of the separations and immobilization processes for selected tank waste. The second step would involve scaling-up the demonstration processes to treat the remaining tank waste and construction of larger treatment facilities. The phased implementation approach could be applied to any of the tank waste alternatives involving ex situ waste treatment; however, for the purposes of analysis the Ex Situ Intermediate Separations alternative, with some additional separations, was selected as the representative alternative. The Phased Implementation alternative is presented in two parts, Phase 1 first, then Phase 2.

E.11.1 PHASE 1

Phase 1 would consist of one LAW treatment facility and one LAW and HLW facility using vitrification to produce a stabilized waste form to specification. This alternative would involve constructing and operating vitrification and support facilities, and transfer lines from the tank farms and T Plant to the vitrification facilities. This alternative would also involve vehicle traffic of the personnel required to support the alternative. This section analyzes the construction, operation, and transportation risks associated with this alternative.

E.11.1.1 Construction Accidents

The potential exists for accidents resulting from construction activities. The construction activities are outlined in Appendix B of the EIS. It should be noted there are no radiological or chemical consequences associated with construction accidents. Occupational injuries, illnesses, and fatalities resulting from potential construction accidents are calculated as follows.

The number of construction personnel was estimated at an average 1.07E+04 person-years (Jacobs 1996). The number of total recordable injuries and illnesses, lost workday cases, and fatalities during construction were calculated using the incidence rates from Table E.1.2.1 as follows:

Total Recordable Cases = (1.07E+04 person-years) · (9.75E+00 incidences/100 person-years) = 1.04E+03

Lost Workday Cases = (1.07E+04 person-years) · (2.45E+00 incidences/100 person-years) = 2.62E+02

Fatalities = (1.07E+04 person-years) · (3.2E-03 fatalities/100 person-years) = 3.42E-01

E.11.1.2 Transportation Accidents

Transportation activities associated with this alternative are:

- Transporting construction material to the Hanford Site;
- Transporting earthen material from onsite borrow sites;
- Transporting process material from offsite to the vitrification facilities;
- Transporting vitrified and unvitrified LAW and HLW to the Canister Storage Building (CSB);
- Transporting contaminated waste from decommissioned facilities to low-level waste burial ground;
- Transporting noncontaminated waste from decommissioned facilities to regulated landfill; and
- Employees commuting to work each day.

E.11.1.2.1 Radiological Cancer Risk from Transportation

Canisters of Cs and technetium would be transported to the CSB by truck. The radiological cancer risk from this activity was compared to a similar activity in Section E.14.2.1. Section E.14.2.1 evaluated the radiological cancer risk from transporting Cs and Sr capsules from WESF to an onsite vitrification facility. The radiological cancer risk from transporting 1.93E+03 of Cs and Sr capsules to the vitrification facility was analyzed (Green 1995) and summarized in Section E.14.2.1 of this appendix. The estimated number of LCFs in an integrated population, resulting from an accident, was 1.2E-05. Approximately half as many Cs and technetium canisters would be transported to the CSB in the Phase 1, therefore 1.2E-05 LCFs would be reduced by a factor of two resulting in approximately 6.0E-06 LCFs for the Phased Implementation alternative.

E.11.1.2.2 Chemical Exposure from Transportation Accidents

The chemical exposure from transportation accidents would be bound by the analysis preformed in Section 6.2.2. The chemical exposure and frequency of the integrated accident was reproduced in Table E.11.1.1. The comparison of exposure concentration from postulated chemical released to exposure limits was reproduced in Table E .11.1.2.

Table E.11.1.1 Chemical Releases from Postulated Accidents for Phase 1

Table E.11.1.2 Comparison of Chemical Concentrations to Corrosive/Irritant Concentration Limits for Phase 1

For the MEI general public the ratio of exposure to ERPG-3 values for corrosive/irritant chemicals was 1.24E+01, which exceed the acceptable criterion of 1.0 and is indicative of potential lethal effects. This acute hazard index is primarily attributable to anhydrous ammonia (over 99.9 percent of the total hazard).

E.11.1.2.3 Occupational Injuries and Fatalities

Truck and Rail Transportation

Injuries and fatalities resulting from direct impact of transportation accidents are analyzed in this subsection. Rail and truck transportation activities to transport materials and supplies to the Site for this alternative were estimated (WHC 1995j) and are summarized in Table E.11.1.3.

Table E.11.1.3 Summary of Transportation Activities for the Phase 1 Alternative

The number of injuries and fatalities were calculated by multiplying the total distance traveled in each zone shown in Table E.11.1.4 by the appropriate unit risk factors shown in Table E.1.3.1. The distance traveled in the population zones were calculated using the methodology previously discussed in Section E.1.3. The expected injuries and fatalities resulting from transportation accidents associated with Phase 1 are summarized in Table E.11.1.5.

Table E.11.1.4 Distance Traveled in Population Zones for Phase 1

Table E.11.1.5 Injuries and Fatalities Resulting from Truck and Rail Transportation Accidents for Phase 1

Employee Traffic

In addition to transporting materials and supplies to and from the Hanford Site by truck and rail, Site workers and other personnel required to perform the various activities would be driving to the site in their vehicles. The total person-years to perform the activities was estimated at 1.76E +04.

Each person was assumed to work 260 days of the year. The round-trip distance traveled to work from the Tri-Cities area was estimated at 140 km (87 mi) with an estimated 1.35 passengers per vehicle (DOE 1994a). The total employee vehicle distance was therefore calculated as follows:

(1.76E+ 04 person-years) · (260 days/year) · (140 km/day) · (1/1.35 passengers per vehicle) = 4.76E+08 km (2.96E+08 mi)

To calculate the expected number of injuries and fatalities resulting from vehicle accidents, the injury/fatality rates discussed in Section E.1.3 were used. The expected number of injuries and fatalities resulting from employee vehicle accidents were calculated as follows:

Injuries = (4.76E+08 km) · (7.1E-07 injuries/km) = 3.40E+02

Fatalities = (4.76E+08 km) · (8.98E-09 fatalities/km) = 4.27E+00

Cumulative Transportation Injuries and Fatalities

The cumulative nonradiological and nontoxicological injuries and fatalities incurred as a direct result of traffic accident impacts are the sum of the truck and rail transport and employee vehicle accidents. The results are summarized in Table E.11.1.6.

Table E.11.1.6 Cumulative Injuries and Fatalities from Traffic Impacts for Phase 1

E.1 1 .1.3 Operation Accidents

Operations are discussed in Appendix B. The radiological and chemical operation accidents, consequences, and risk for Phase 1 are summarized in the following text.

E.11.1.3.1 Continued Operation Accidents - Mispositioned Jumper Accident - Tank waste Transfer

The dominant continued operations accident during tank waste transfer is the mispositioned jumper accident previously discussed in the No Action alternative in Section E.2.2.1 and summarized as follows:

Source-Term - The source-term resulting from a spray release in Section E.2.2.1.1 was calculated to be 52 L (14 gal).

Probability - The frequency of a mispositioned jumper in Section E.2.2.1.2 was 1.1E-02 per year. The probability of the No Action alternative was based upon 10 years of waste transfers. Phase 1 is based on 10 years of operations; therefore, the probability would be the same 1.1E-01.

Radiological Consequences - The radiological consequences presented in Table E.2.2.2 are reproduced in Table E. 11.1.7.

Table E.11.1.7 Dose Consequence from Mispositioned Jumper

Radiological Cancer Risk - The LCFs calculated in Section E.2.2.1.4 are the same for Phase 1 and are reproduced in Table E.11.1.8. The bounding scenario calculations show that all 10 workers would potentially receive a fatal dose and assumably die directly after the exposure if the accident occurred.

Table E.11.1.8 Latent Cancer Fatality Risk from Mispositioned Jumper

There would be approximately seven LCFs from the noninvolved worker population and two from the general public. The nominal scenario calculations show there would be no LCFs.

Chemical Consequences

Potential acute hazards associated with a mispositioned jumper are identical to those summarized in Tables E.2.2.4 (toxic chemicals, nominal conditions), E.2.2.5 (toxic chemicals, bounding conditions), E.2.2.6 (corrosive/irritant chemicals, nominal conditions) and E.2.2.7 (corrosive/irritant chemicals, bounding conditions) for the No Action alternative.

Toxic Impact from Chemical Exposure

Under nominal conditions (Table E.2.2.4), the cumulative acute hazard ratios for the MEI worker, MEI noninvolved worker and MEI general public were less than 1.0, indicating that no adverse acute health effects would be expected for these three receptors. Under bounding conditions (Table E.2.2.5), the MEI worker was not evaluated because death would occur from exposure to radionuclides. The cumulative acute hazard ratio for the MEI noninvolved worker was 5.36E+00 for ERPG-2, indicating that reversible acute health effects would be expected. This acute hazard ratio was primarily attributable to mercury (approximately 89 percent of the overall hazard ratio). No adverse acute health effects were predicted for the MEI general public under bounding conditions.

Corrosive/Irritant Impact from Chemical Exposure

Under nominal conditions (Table E.2.2.6), the cumulative acute hazard ratio for the MEI worker was 2.70E+00 for ERPG-3, indicating the potential for irreversible health effects that could be life threatening. This acute hazard ratio was almost entirely attributable to sodium assumed to be equivalent to sodium hydroxide in corrosive/irritant effects. For the MEI noninvolved worker, the cumulative acute hazard ratio for ERPG-1 was 3.00E+00, indicating that only mild, reversible, irritant effects would be expected. No acute health impacts were predicted for the MEI general public under nominal conditions. Under bounding conditions (Table E.2.2.7), the MEI worker was not evaluated because death would occur from exposure to radionuclides. For the MEI noninvolved worker, the cumulative acute hazard ratio for ERPG-1 was 4.36E+00, indicating that only mild, reversible, irritant effects would be expected. No acute health impacts were predicted for the MEI general public under bounding conditions.

Under both nominal and bounding conditions, the probability of a mispositioned jumper is 1.10E-01.

E .11.1.3.2 Pretreatment Accidents

The dominant pretreatment operations accident is the seismic induced line break in vault accident previously discussed in the Ex Situ Intermediate Separations alternative in Section E.6.3. 4 and is summarized as follows:

Source-Term - The source-term resulting from the airborne release in Section E.6.3. 4 .1 was calculated to be 7.3E-02 L (6.6E-02 gal).

Probability - The annual excedance frequency of the seismic event in Section E.6.3. 4 .2 was 6.5 E-0 4 per year. Phase 1 was based on 10 years of operations; therefore, the probability was calculated to be 6. 5 E-0 3 .

Radiological Consequences - The radiological consequences presented in Section 6.3. 4 .3 are reproduced in Table E.11.1.9.

Table E.11.1.9 Dose Consequence from Seismic Induced Line Break in Vault

Radiological Cancer Risk - The LCFs and the LCF point estimate risk were calculated for the receptors and presented in Table E.11.1.10. The calculations show that there would be no LCFs attributable to this exposure if the accident occurs for the bounding and nominal scenarios .

Table E.11.1.10 Latent Cancer Fatality Risk from Seismic Induced Line Break in Vault

Chemical Consequences

The chemical exposure to the receptors from the postulated accident was calculated in Appendix A of the accident data package (Shire et al. 1995 and Jacobs 1996) and summarized in the exposure column in Tables E.6.3.14 and E.6.3.15 for the nominal and bounding toxic effects, respectively, and Tables E.6.3.16 and E.6.3.17 for the nominal and bounding corrosive/irritant effects, respectively. The tables compare the concentration of postulated chemical releases to acute exposure criteria (ERPGs) discussed in Section 1.1.7.

Toxic Impact from Chemical Exposure

Under nominal conditions (Table E.6.3.14), the cumulative acute hazard ratios for the MEI worker, MEI noninvolved worker, and MEI general public were less than 1.0, indicating that no adverse acute health effects would be expected for these three receptors. Under bounding conditions (Table E.6.3.15), the cumulative acute hazard ratios for the MEI worker, MEI noninvolved worker, and MEI general public were less than 1.0, indicating that no adverse acute health effects would be expected for these three receptors.

Corrosive/Irritant Impact from Chemical Exposure

Under nominal conditions (Table E.6.3.16), the cumulative acute hazard ratios for the MEI worker, MEI noninvolved worker and MEI general public were less than 1.0, indicating that no adverse acute health effects would be expected for these three receptors. Under bounding conditions (Table E.6.3.17), the cumulative acute hazard ratios for the MEI worker, MEI noninvolved worker, and MEI general public were less than 1.0, indicating that no adverse acute health effects would be expected for these three receptors.

Under both nominal and bounding conditions, the probability of a pretreatment spray release is 6.50E-03.

E.11.1.3.3 Treatment Accidents

The dominant treatment operations accident is a crushed Cs canister. It was postulated that the Cs canister is breached when a heavy object falls on the canister. The source-term, probability, and dose consequences were taken from (WHC 1995k) and summarized in the following text.

Scenario and Source-Term Development

It was assumed that the initial shock of the drop of a heavy object on the canister would spill the entire canister contents and loft a fraction of 1.0E-03 of the activity by free-fall. This would be resuspended for 8 hours at 4.0E-06 per hour and released from the facility through two stage HEPA filters that would provide a LPF of 2.0E-06. The source-term would be 8.0E-05 Ci.

Probability

The scenario was considered to be unlikely with a frequency range of 1.0E-02 per year to 1.0E-04 per year. For conservatism, a frequency of 1.0E-02 per year was used for calculating risk. Based on a separations operation of 10 years, the probability was calculated to be 1.0E-01.

Radiological Consequences

The radiological dose to the receptors from the accident scenario was calculated using the methodology previously discussed in Section 1.1.6. The results are summarized in Table E.11.1.11. Dose consequences for the worker was not evaluated since the accident was assumed to take place in a vault and would result in a filtered stack release.

Table E.11.1.11 Dose Consequence from Crushed Cesium Canister

Radiological Cancer Risk

Based on a dose-to-risk conversion factor of 4.0E-04 LCF per person-rem for the workers and noninvolved workers and 5.0E-04 LCF per person-rem for the general public, the LCFs and the LCF point estimate risk were calculated for the receptors and presented in Table E.11.1.12 . The calculations show there would be no LCFs attributable to this exposure if the accident occurs.

Table E.11.1.12 Latent Cancer Fatality Risk from Crushed Cesium Canister

Chemical Exposure

Chemical exposure was not evaluated since there would essentially be no other chemical in the canister other than Cs which was evaluated under Radiological consequences.

E.11.1.3.4 Disposal/Storage Accidents

No DBA accidents resulting in a radiological or chemical consequences to the receptors were identified. This is largely due to the vitrified waste form of the material and the engineered structural packaging of the vitrified LAW and vitrified HLW in shipping containers.

E.11.1.3.5 Occupational Injuries and Fatalities

The number of operation personnel to support Phase 1 was estimated at 6.93E+03 (Jacobs 1996). The total recordable injuries and illnesses, lost workday cases, and fatalities were calculated as follows:

Total Recordable Cases = (6.93E+03 person-years) · (2.2E+00 incidences/100 person-years) = 1.52E+02

Lost Workday Cases = (6.93E+03 person-years) · (1.1E+00 incidences/100 person-years) = 7.62E+01

Fatalities = (6.93E+03 person-years) · (3.2E-03 fatalities/100 person-years) = 2.22E-01

E.11.2 TOTAL ALTERNATIVE

The Total alternative for tank waste would involve constructing and operating vitrification and support facilities, low-activity vitrified waste burial vaults, and transfer lines from the tank farms and T Plant to the vitrification facilities. This alternative would also involve transporting retrieved tank waste to a vitrification facility, and vehicle traffic of the personnel required to support the alternative. This section analyzes the construction, operation, and transportation risks associated with this alternative.

E.11.2.1 Construction Accidents

The potential exists for accidents resulting from construction activities. The construction activities are outlined in Appendix B of the EIS. It should be noted there are no radiological or chemical consequences associated with construction accidents. Occupational injuries, illnesses, and fatalities resulting from potential construction accidents are calculated as follows.

The number of construction personnel was estimated at an average 4.82E+04 person-years (Jacobs 1996). The number of total recordable injuries and illnesses, lost workday cases, and fatalities during construction were calculated using the incidence rates from Table E.1.2.1 as follows:

Total Recordable Cases = (4.82E +04 person-years) · (9.75E+00 incidences/100 person-years) = 4.70E+03

Lost Workday Cases = (4.82E +04 person-years) · (2.45E+00 incidences/100 person-years) = 1.18E+03

Fatalities = (4.82E +04 person-years) · (3.2E-03 fatalities/100 person-years) = 1.54E+00

E.11.2.2 Transportation Accidents

Under the Total alternative, Hanford Site tank waste would be stabilized by vitrification. The residual SST waste and MUST waste would be transported to a vitrification facility. In addition to transporting the waste, construction materials and process chemicals would be transported to the Hanford Site by truck and rail. This alternative would also be supported by a work force of employees that would commute to work each day.

E.11.2.2.1 Radiological Cancer Risk

The radiological cancer risk would be the same as that previously discussed in Section E.6.2.1. for truck transport of retrieved tank waste to the vitrification facility.

The receptor dose, LCFs, and LCF risk resulting from a truck transport accident during retrieval of MUST waste and SST residuals for the integrated population and for the MEI worker and MEI general public was evaluated in Section E.6.2.1.1. These are reproduced in Tables E.11.2.1 and E.11.2.2.

Table E.11.2.1 Integrated Radiological Impact from Retrieval Transport Accidents

Table E.11.2.2 Maximally-Exposed Individual Radiological Impact from Retrieval Transport Accidents

There would be no LCFs resulting from an accident while transporting retrieved waste on site.

E.11.2.2.2 Chemical Exposure

Chemicals transported to the Hanford Site to support the pretreatment and vitrification processes would have the greatest chemical impact. The impacts were previously analyzed in Section E.6.2.2. The evaluation showed the general public exposure to anhydrous ammonia would exceed the ratio of exposure to ERPG-3 by 1.24E+01 and sodium hydroxide would exceed the ratio of exposure to ERPG-1 by 2.45E+00 for corrosive/irritant chemicals. The magnitude of the anhydrous ammonia exceedance indicates potential lethal effects for the MEI general public.

E.11.2.2.3 Occupational Injuries and Fatalities

Truck and Rail Transportation - Injuries and fatalities resulting from direct impact of transportation accidents are analyzed in this subsection. Rail and truck transportation activities to transport materials and supplies to the Site for this alternative were estimated (WHC 1995j) and are summarized in Table E.11.2.3.

Table E.11.2.3 Summary of Transportation Activities for the Total Alternative

The number of injuries and fatalities were calculated by multiplying the total distance traveled in each zone shown in Table E.11.2.4 by the appropriate unit risk factors shown in Table E.1.3.1.

Table E.11.2.4 Distance Traveled in Population Zones for the Total Alternative

The distance traveled in the population zones were calculated using the methodology previously discussed in Section E.1.3. The expected injuries and fatalities resulting from transportation accidents associated with the Total alternative are summarized in Table E.11.2.5.

Table E.11.2.5 Injuries and Fatalities Resulting from Truck and Rail Transportation Accidents for the Total Alternative

Employee Traffic - In addition to transporting materials and supplies to and from the Hanford Site by truck and rail, Site workers and other personnel required to perform the various activities would be driving to the site in their vehicles. The total person-years to perform the activities was estimated at 1.32E+05 (Jacobs 1996).

Each person was assumed to work 260 days of the year. The round-trip distance traveled to work from the Tri-Cities area was estimated at 140 km (87 mi) with an estimated 1.35 passengers per vehicle (DOE 1994a). The total employee vehicle distance was therefore calculated as follows:

$$(1.32E+05 \text{ person-years}) \cdot (260 \text{ days/year}) \cdot (140 \text{ km/day}) \cdot (1/1.35) = 3.56\ E+09 \text{ km } (2.21\ E+09 \text{ mi}).$$

To calculate the expected number of injuries and fatalities resulting from vehicle accidents, the injury/fatality rates discussed in Section E.1.3 were used. The expected number of injuries and fatalities resulting from employee vehicle accidents were calculated as follows:

$$\text{Injuries} = (3.56E+09 \text{ km}) \cdot (7.1E\text{-}07 \text{ injuries/km}) = 2.54E+03$$

Fatalities = (3.56E +09 km) · (8.98E-09 fatalities/km) = 3.19E +01

Cumulative Transportation Injuries and Fatalities - The cumulative nonradiological and nontoxicological injuries and fatalities incurred as a direct result of traffic accident impacts are the sum of the truck and rail transport and employee vehicle accidents. The results are summarized in Table E.11.2.6.

Table E.11.2.6 Cumulative Injuries and Fatalities from Traffic Impacts for the Total Alternative

E.11.2.3 Operation Accidents

Operation accidents would be the same as those analyzed in Section E.6.3.

E.11.2.3.1 Routine Operation Accidents - Tank Waste Transfers

The dominant routine operations accident during tank waste transfers is the mispositioned jumper accident previously discussed in the No Action alternative in Section E.2.2.1 and summarized as follows:

Source-Term - The source-term resulting from a spray release in Section E.2.2.1.1 was calculated to be 52 L (14 gal).

Probability - The frequency of a mispositioned jumper in Section E.2.2.1.2 was 1.1E-02 per year. The Ex Situ Intermediate Separations alternative was based on 27.5 years of operations; therefore, the probability was calculated to be 3.0E-01.

Radiological Consequences - The radiological consequences presented in Table E.2.2.2 are reproduced in Table E.11.2.7.

Table E.11.2.7 Dose Consequence from Mispositioned Jumper

Radiological Cancer Risk - The LCFs calculated in Section E.2.2.1.4 are the same for the Total alternative. However, the LCF risk (point estimate) is not the same due to the difference in probabilities. The LCFs and the LCF risk are calculated in Table E.11.2.8. The bounding scenario calculations show that all 10 workers would potentially receive a fatal dose and assumably die directly after the exposure if the accident occured. There would be approximately seven LCFs from the noninvolved worker population and two from the general public. The nominal scenario calculations show there would be no LCFs.

Chemical Consequences

Potential acute hazards associated with a mispositioned jumper are identical to those summarized in Tables E.2.2.4 (toxic chemicals, nominal conditions), E.2.2.5 (toxic chemicals, bounding conditions), E.2.2.6 (corrosive/irritant chemicals, nominal conditions) and E.2.2.7 (corrosive/irritant chemicals, bounding conditions) for the No Action alternative.

Table E.11.2.8 Latent Cancer Fatality Risk from Mispositioned Jumper

Toxic Impact from Chemical Exposure

Under nominal conditions (Table E.2.2.4), the cumulative acute hazard ratios for the MEI worker, MEI noninvolved worker, and MEI general public were less than 1.0, indicating that no adverse acute health effects would be expected for these three receptors. Under bounding conditions (Table E.2.2.5), the MEI worker was not evaluated because death would occur from exposure to radionuclides. The cumulative acute hazard ratio for the MEI noninvolved worker was 5.36E+00 for ERPG-2, indicating that reversible acute health effects would be expected. This acute hazard ratio was primarily attributable to mercury (approximately 89 percent of the overall hazard ratio). No adverse acute health effects were predicted for the MEI general public under bounding conditions.

Corrosive/Irritant Impact from Chemical Exposure

Under nominal conditions (Table E.2.2.6), the cumulative acute hazard ratio for the MEI worker was 2.70E+00 for ERPG-3, indicating the potential for irreversible health effects that could be life-threatening. This acute hazard ratio was almost entirely attributable to sodium assumed to be equivalent to sodium hydroxide in corrosive/irritant effects. For the MEI noninvolved worker, the cumulative acute hazard ratio for ERPG-1 was 3.00E+00, indicating that only mild, reversible, irritant effects would be expected. No acute health impacts were predicted for the MEI general public under nominal conditions. Under bounding conditions (Table E.2.2.7), the MEI worker was not evaluated because death would occur from exposure to radionuclides. For the MEI noninvolved worker, the cumulative acute hazard ratio for ERPG-1 was 4.36E+00, indicating that only mild, reversible, irritant effects would be expected. No acute health impacts were predicted for the MEI general public under bounding conditions.

Under both nominal and bounding conditions, the probability of a mispositioned jumper is 3.03E-01.

E.11.2.3.2 Continued Operations Accidents - Waste Storage Tanks

The dominant accident is a hydrogen deflagration in a waste storage tank previously discussed in the No Action alternative in Section E.2.2.2.1 and is summarized as follows.

Source-Term - The source-term resulting from the fire in Section E.2.2.2.1 was calculated to be 2.5E-01 L (6.6E-02 gal).

Probability - The frequency of the hydrogen deflagration in a waste storage tank in Section E.2.2.2.2 was estimated to be 7.2E-03 per year. The probability of the scenario based on 31 years of operation was therefore estimated to be 2.23E-01.

Radiological Consequences - The radiological consequences presented in Table E.2.2.8 are reproduced in Table E.11.2.9.

Table E.11.2.9 Dose Consequence from Hydrogen Deflagration in Waste Storage Tank

Radiological Cancer Risk - The LCFs calculated in Section E.2.2.2.4 are the same for the Total alternative. However, the LCF risk (point estimate) is not the same due to the difference in probabilities. The LCR and the LCF risk are calculated in Table E.11.2.10.

In the bounding scenario all 10 workers would potentially receive a fatal dose and assumably die directly after the exposure. There would also be 10 LCFs attributed to the exposure to the noninvolved workers and 2 LCFs to the general public if the accident occurred. The nominal scenario calculations show that there would be no LCFs.

Table E.11.2.10 Latent Cancer Fatality Risk from Hydrogen Deflagration in Waste Storage Tank

Chemical Consequences

Potential acute hazards associated with a hydrogen burn in a waste storage tank are identical to those summarized in Tables E.2.2.10 (toxic chemicals, nominal conditions), E.2.2.11 (toxic chemicals, bounding conditions), E.2.2.12 (corrosive/irritant chemicals, nominal conditions) and E.2.2.13 (corrosive/irritant chemicals, bounding conditions) for the No Action alternative.

Under bounding conditions, chemical impacts were not evaluated for the MEI worker because all workers would receive a lethal radiation dose as discussed previously.

Toxic Impact from Chemical Exposure

Under nominal conditions (Table E.2.2.10), the cumulative acute hazard ratio for the MEI worker was 1.57E+00 for ERPG-2, indicating that reversible acute health effects would be expected. This acute hazard ratio was primarily attributable to TOC (approximately 87 percent of the overall ERPG-2 ratio). The TOC is assumed to be equivalent in toxicity to tributylphosphate, which is the most acutely toxic constituent of the organic analytes identified. Tributylphosphate was used as a surrogate because an inventory of the various chemicals that make up the TOC class is not available. For the MEI noninvolved worker, the cumulative acute hazard ratio for ERPG-3 was 9.38E+00, indicating the potential for irreversible health effects that could be life threatening. This acute hazard ratio was also primarily attributable to TOC (approximately 90 percent of the overall ERPG-3 ratio) However, the MEI noninvolved worker is a hypothetical worker assumed to be located 100 m (330 ft) from the source area. The nearest noninvolved worker population is located 290 m (950 ft) from the source area and had no cumulative acute hazard ratios greater than 1.0 for any of the ERPGs, indicating that no acute health effects would be expected for the nearest noninvolved worker population. Likewise, no acute health effects were predicted for the MEI general public under nominal conditions.

Under bounding conditions (Table E.2.2.11), the cumulative acute hazard ratio for the MEI noninvolved worker was 4.54E+02 for ERPG-3, indicating the potential for irreversible health effects that could be life-threatening. This acute hazard ratio is primarily attributable to:

- Oxalate (approximately 37 percent of the total hazard ratio);
- Beryllium (approximately 13 percent of the total hazard ratio);
- Cadmium (approximately 14 percent of the total hazard ratio);
- Uranium (approximately 12 percent of the total hazard ratio); and
- TOC (approximately 8 percent of the total hazard ratio).

As discussed previously, this is a hypothetical receptor located 100 m (330 ft) from the source. The cumulative acute hazard ratio for the nearest noninvolved worker population located 290 m (950 ft) from the source was 1.65E+00 for ERPG-3, indicating the potential for irreversible health effects that could be life threatening for 335 workers. This hazard ratio was attributable to the same toxic chemicals listed above.

This exceedance of the ERPG-3 criterion for the nearest noninvolved worker population would not be expected to result in irreversible health effects or place these workers in a life-threatening situation for the following reasons.

- ERPG-3 is defined as a concentration in which a receptor can be exposed for 1 hour without irreversible health effects. Because the Hanford Site has an in-place emergency response plan designed to evacuate workers within 1 hour of an accident, workers would be expected to evacuate their location and move to an area where potential exposures would be well below ERPG-3. Therefore, this worker population would not be exposed to airborne concentrations that would be either life threatening or result in irreversible health effects.
- The estimated air concentrations of chemicals as a result of this accident were based on very conservative meteorology, which results in movement of a plume directly toward the worker population at a relatively slow rate with minimal wind dispersion. If less conservative meteorological parameters were used, wind dispersion would cause the estimated air concentrations of chemicals to be substantially less, and the ERPG-3 criterion would not be exceeded.
- Only the bounding toxic chemical evaluation exceeded ERPG-3, while the nominal evaluation was well below 1.00E+00 for ERPG-3, suggesting that the noninvolved worker population would not receive an exposure that would result in any permanent health effects.

The next nearest noninvolved worker population is located 1,780 m (5,840 ft) from the source and contains 1,500 workers. The cumulative acute hazard ratio was less than 1.0 for all ERPGs, indicating that no acute health effects would be expected for this population of workers. No acute health impacts were predicted for the MEI general public.

Corrosive/Irritant Impact from Chemical Exposure

Under nominal conditions (Table E.2.2.12), the cumulative acute hazard ratio for the MEI worker was 3.82E+00 for ERPG-3, indicating the potential for irreversible corrosive/irritant effects that could be life threatening. For the MEI noninvolved worker, the cumulative acute hazard ratio for ERPG-3 was 7.89E+01 and would indicate irreversible corrosive/irritant effects that could be life threatening for this hypothetical receptor. This hazard ratio was primarily attributable to sodium, which was assumed to be equivalent to sodium hydroxide in corrosive/irritant effects. For the nearest noninvolved worker population (290 m [950 ft]) composed of 335 workers, the cumulative acute hazard ratio for ERPG-1 was 1.38E+01, indicating that only mild, reversible effects would be expected. No acute health impacts were predicted for the MEI general public under nominal conditions.

Under bounding conditions (Table E.2.2.13), the cumulative acute hazard ratio for the MEI noninvolved worker was 1.91E+02 for ERPG-3, indicating irreversible health effects that could be life threatening for this hypothetical receptor. This hazard ratio was primarily attributable to :

- Sodium as sodium hydroxide (approximately 75 percent of the total hazard ratio);
- Chromium (approximately 14 percent of the total hazard ratio); and
- Calcium (approximately 6 percent of the total hazard ratio).

For the nearest noninvolved worker population (290 m [950 ft]) composed of 335 workers, the cumulative acute hazard ratio was 1.74E+00 for ERPG-2, indicating that reversible acute effects would be expected. No acute health impacts were predicted for the MEI general public under nominal conditions.

Under both nominal and bounding conditions, the probability of a hydrogen deflagration event in a waste storage tank is 2.23E-01.

E.11.2.3.3 Retrieval Accidents

The dominant routine operations accident is the loss of filtration accident previously discussed in the Ex Situ Intermediate Separations alternative in Section E.6.3. 3 and summarized as follows:

Source-Term - The source-term resulting from a loss of filtration in Section E.6.3. 3 .1 was calculated to be 2.5E-01 L (6.6E-02 gal).

Probability - The frequency of a loss of filtration in Section E.6.3. 3 .2 was 8.8E-06 per year. The Total alternative retrieval activity was based on 31 years of operation, therefore the probability was calculated to be 2.7E-04.

Radiological Consequence - The radiological consequences presented in Section E.6.3.3 are reproduced in Table E.11.2.11.

Table E.11.2.11 Dose Consequence for Loss of Filtration

Radiological Cancer Risk - The LCFs calculated in Section E.6.3. 3 .4 are reproduced in Table E.11.2.12. Aside from all 10 workers dying from a lethal dose, the calculations show that there would be no LCFs attributed to the exposure to the noninvolved workers and the general public if the accident occurred.

Chemical Consequences

The chemical exposure to the receptors from the postulated accident was calculated in Appendix A of the accident data package (Shire et al. 1995 and Jacobs 1996) and summarized in the exposure column in Tables E.6.3.8 and E.6.3.9 for the nominal and bounding toxic effects, respectively, and Tables E.6.3.10 and E.6.3.11 for the nominal and bounding corrosive/irritant effects, respectively. The tables compare the concentration of postulated chemical releases to acute exposure criteria (ERPGs) discussed in Section 1.1.7.

Table E.11.2.12 Latent Cancer Fatality Risk from Loss of Filtration

Under bounding conditions, chemical impacts were not evaluated for the MEI worker because all workers would receive a lethal radiation dose, as discussed previously.

Toxic Impact from Chemical Exposure

Under nominal conditions (Table E.6.3.8), the cumulative acute hazard ratio for the MEI worker was less than 1.0 for all ERPGs, indicating that no adverse acute health effects would be expected. For the MEI noninvolved worker, the cumulative acute hazard ratio was 1.84E+00 for ERPG-1, indicating that only mild, transient acute health effects would be expected. No acute health effects were predicted for the MEI general public under nominal conditions.

Under bounding conditions (Table E.6.3.9), the cumulative acute hazard ratio for the MEI noninvolved worker was 7.27E+01 for ERPG-3, indicating the potential for irreversible health effects that could be life threatening. This acute hazard ratio is primarily attributable to:

- Uranium (approximately 48 percent of the total hazard ratio);
- Oxalate (approximately 24 percent of the total hazard ratio);
- Mercury (approximately 13 percent of the total hazard ratio); and
- TOC (approximately 7 percent of the total hazard ratio).

As discussed previously, this is a hypothetical receptor located 100 m (330 ft) from the source. The cumulative acute hazard ratio for the nearest noninvolved worker population (335 workers) located 290 m (950 ft) from the source was 5.40E+00 for ERPG-2, indicating that reversible acute health effects would be expected. No acute health impacts were predicted for the MEI general public.

Corrosive/Irritant Impact from Loss of Filtration

Under nominal conditions (Table E.6.3.10), the cumulative acute hazard ratio for the MEI worker was 2.11E+00 for ERPG-2, indicating that reversible corrosive/irritant effects would be expected. For the MEI noninvolved worker, the cumulative acute hazard ratio for ERPG-3 was 1.72E+01 and would indicate irreversible corrosive/irritant effects that could be life threatening for this hypothetical receptor. This hazard ratio was primarily attributable to sodium, which was assumed to be equivalent to sodium hydroxide in corrosive/irritant effects. For the nearest noninvolved worker population (290 m) composed of 335 workers, the cumulative acute hazard ratio for ERPG-1 was 3.02E+00, indicating that only mild, transient irritant effects would be expected. No acute health impacts were predicted for the MEI general public under nominal conditions.

Under bounding conditions (Table E.6.3.11), the cumulative acute hazard ratio for the MEI noninvolved worker was 2.47E+01 for ERPG-3, indicating irreversible health effects that could be life threatening for this hypothetical receptor. This hazard ratio was primarily attributable to :

- Sodium as sodium hydroxide (approximately 82 percent of the total hazard ratio); and
- Calcium (approximately 9 percent of the total hazard ratio).

For the nearest noninvolved worker population (290 m [950 ft]) composed of 335 workers, the cumulative acute hazard ratio was 4.38E+00 for ERPG-1, indicating that only mild, transient irritant effects would be expected. No acute health impacts were predicted for the MEI general public under nominal conditions.

Under both nominal and bounding conditions, the probability of a loss of filtration event in a waste storage tank is 2.73E-04 for the MEI worker, MEI noninvolved worker, and MEI general public.

E.11.2.3.4 Pretreatment

The dominant pretreatment operations accident was the line break within a vault due to an earthquake previously discussed in the Ex Situ Intermediate Separations alternative in Section E.6.3.4 and summarized as follows:

Source-Term - The source-term resulting from a line break in a vault in Section E.6.3.4.1 was calculated to be 7.3E-02 L (1.9E-02 gal).

Probability - The probability of a seismic induced line break in Section E.6.3.4.2 was calculated to be 2.02E-02.

Radiological Consequences - The radiological consequences presented in Section E.6.3.4.3 are reproduced in Table E.11.2.13.

Table E.11.2.13 Dose Consequence for Seismic Induced Line Break

Radiological Cancer Risk - The LCFs calculated in Section E.6.3.3.4 are reproduced in Table E.11.2.14 . The calculations show that there would be no LCFs attributable to this exposure if the accident occurs for the bounding and nominal scenarios .

Chemical Consequences

The chemical exposure to the receptors from the postulated accident was calculated in Appendix A of the accident data package (Shire et al. 1995 and Jacobs 1996) and summarized in the exposure column in Tables E.6.3.14 and E.6.3.15 for the nominal and bounding toxic effects, respectively, and Tables E.6.3.16 and E.6.3.17 for the nominal and bounding corrosive/irritant effects, respectively. The tables compare the concentration of postulated chemical releases to acute exposure criteria (ERPGs) discussed in Section E.1.1.7.

Toxic Impact from Chemical Exposure

Under nominal conditions (Table E.6.3.14), the cumulative acute hazard ratios for the MEI worker, MEI noninvolved worker, and MEI general public were less than 1.0, indicating that no adverse acute health effects would be expected for these three receptors. Under bounding conditions (Table E.6.3.15), the cumulative acute hazard ratios for the MEI worker, MEI noninvolved worker, and MEI general public were less than 1.0, indicating that no adverse acute health effects would be expected for these three receptors.

Table E.11.2.14 Latent Cancer Fatality Risk from Seismic Induced Line Break in Vault

Corrosive/Irritant Impact from Chemical Exposure

Under nominal conditions (Table E.6.3.16), the cumulative acute hazard ratios for the MEI worker, MEI noninvolved worker and MEI general public were less than 1.0, indicating that no adverse acute health effects would be expected for these three receptors. Under bounding conditions (Table E.6.3.17), the cumulative acute hazard ratios for the MEI worker, MEI noninvolved worker, and MEI general public were less than 1.0, indicating that no adverse acute health effects would be expected for these three receptors.

Under both nominal and bounding conditions, the probability of a pretreatment spray release is 2.02E-02 .

E.11.2.3.5 Treatment Accidents

The dominant routine operations accident is an inadvertent HLW canister drop discussed in the Ex Situ Intermediate Separations alternative in Section E.6.3.4 and summarized as follows:

Source-Term from Breached Canister - The source-term in Section E.6.3. 5 .1 was 2.5E-06 grams (8.8E-08 ounces).

Probability - The probability of dropping a canister in Section E.6.3. 5 .3 was calculated to be 1.0E+00.

Radiological Consequences - The radiological consequences presented in Section E.6.3.5.4 are reproduced in Table E.11.2.15

Table E.11.2.15 Dose Consequence from Breached Canister

Radiological Cancer Risk - The LCFs calculated in Section 6.3. 5 .4 are reproduced in Table E.11.2.16. The calculations show there would be no LCFs attributable to this exposure for bounding and nominal scenarios .

Chemical Consequences - No chemical consequences were evaluated in (Shire et al. 1995 and Jacobs 1996) since the release would first pass through two-stage HEPA filters that would reduce the source-term to a very small amount, well below the cumulative ratio of exposure to ERPG-1 values for toxic or corrosive/irritant chemicals.

E.11.2.3.6 Disposal/Storage Accidents

No DBA accidents resulting in radiological or chemical consequences to the receptors were identified. This is largely due to the vitrified waste form of the material and the engineered structural packaging of the vitrified LAW in burial vaults and vitrified HLW in shipping containers.

TableE.11.2.16 Latent Cancer Fatality Risk from Breached Canister

E.11.2.3.7 Beyond Design Basis Accidents

The beyond design basis accident is a seismic event resulting in the collapse of a SST. In the event of a 0.43 g earthquake, a SST could potentially collapse (LANL 1995). This event is not dependent on the remediation alternative but has the same annual frequency regardless of the alternative that is chosen.

The length of time unremediated waste would remain in tanks that have not been backfilled would vary depending on the alternative and would affect the probability of the event. The probability of the event is the product of the annual frequency of the earthquake and the number of years the waste remains untreated in the unstabilized tanks.

At smaller annual frequencies, larger earthquakes could occur resulting in greater destruction and larger numbers of LCF to the onsite and offsite populations. In addition to population exposures from the collapsed SSTs, the impact to other Hanford Site facilities and operations would potentially add to the chemical and radiological risk. This would be a severe earthquake that would cause catastrophic structural damage in the Tri-Cities and the Hanford Site with expected extensive loss of life. There would be injuries and fatalities resulting from collapsed buildings and homes, fires, and traffic accidents. However, this section evaluates the radiological and chemical impacts resulting from the collapse of one SST.

E.11.2.3.8 Source-Term Development

It was conservatively assumed that the radiological and chemical contaminants in the headspace are available for release. The collapse of a portion of the dome and overburden compresses the vapor in the headspace as it descends, enhancing the vapor release rate by a sudden pressure difference. Assuming for each tank a respirable concentration of contaminants in the headspace of 100 mg/m^3, a liquid SpG of 1.5, and a headspace volume of 1,000 m^3 (Shire et al. 1995 and Jacobs 1996), the potential source-term contribution from the headspace release was calculated as follows:

$$(100\ \text{mg/m}^3) \cdot (1\ \text{g}/1{,}000\ \text{mg}) \cdot (1\ \text{L}/1{,}000\ \text{g}) \cdot (1{,}000\ \text{m}^3) \cdot (1/1.5) = 6.67\text{E-}02\ \text{L}\ (1.8\text{E-}02\ \text{gal}).$$

It was conservatively assumed that the liquids had been pumped from the tanks so that the tanks contained only solids and the MAR was 2,500 L (660 gal) for each tank. It was postulated that the fall of the dome and overburden generated an air movement sufficient to suspend a fraction the MAR. Assuming the respirable release fraction to be 2.0E-03 (Shire et al. 1995 and Jacobs 1996), the potential source-term contribution was calculated as follows:

$$(2{,}500\ \text{L}) \cdot (2.0\text{E-}03) = 5\ \text{L}\ (1.3\ \text{gal}).$$

It was postulated that prevailing winds resuspend a respirable fraction of the MAR (2,500 L [660 gal]). A respirable release fraction of 4.0E-05/hr for 24 hours was assumed. The potential source-term contribution from resuspension was calculated as follows:

$$(2{,}500\ \text{L}) \cdot (4.0\text{E-}05/\text{hr}) \cdot (24\ \text{hr}) = 2.4\ \text{L}\ (0.6\ \text{gal}).$$

The combined source-term for the acute release is calculated as follows:

$$(6.67\text{E-}02\ \text{L}) + (5.0\ \text{L}) + (2.4\ \text{L}) = 7.4\ \text{L}\ (2.0\ \text{gal}).$$

E.11.2.3.9 Probability of a Beyond Design Basis Earthquake

This earthquake has a calculated annual exceedance frequency of approximately 1.40E-04 (WHC 1996b). The probability for this scenario based on 31 years of operation was therefore estimated to be 4.3E-03.

E.11.2.3.10 Radiological Consequences from a Beyond Design Basis Earthquake

The radiological dose to the receptors from the previous source-term was calculated by the GENII computer code (Napier et al. 1988) using the methodology previously discussed in Section E.1.1.6. The results are presented in Table E.11.2.17.

E.11.2.3.11 Radiological Cancer Risk from a Beyond Design Basis Earthquake

The LCFs and LCF point estimate risk are presented in Table E.11.2.18.

Table E.11.2.17 Dose Consequence from Seismic Event

Table E.11.2.18 Latent Cancer Fatality Risk from Seismic Event

In the bounding scenario, all 10 workers would potentially receive a fatal dose and assumably die directly after the exposure. There would also be 10 LCFs attributed to the exposure to the noninvolved workers and two LCFs to the general public if the accident occurred. The nominal scenario calculations show there would be no LCFs.

E.11.2.3.12 Chemical Consequences from a Beyond Design Basis Earthquake

Potential acute hazards associated with a beyond design basis earthquake are identical to those summarized in Tables E.2.2.16 (toxic chemicals, nominal conditions), E.2.2.17 (toxic chemicals, bounding conditions), E.2.2.18 (corrosive/irritant chemicals, nominal conditions) and E.2.2.19 (corrosive/irritant chemicals, bounding conditions) for the No Action alternative.

Under bounding conditions, chemical impacts were not evaluated for the MEI worker because all workers would receive a lethal radiation dose, as described previously.

Toxic Impact from Chemical Exposure

Under nominal conditions, the cumulative acute hazard ratio for the MEI worker was 2.64E+00 for ERPG-1, indicating that only mild transient effects would be expected. For the MEI noninvolved worker, the cumulative acute health hazard was 2.59E+00 for ERPG-3, indicating the potential for irreversible health effects that could be life threatening. This acute hazard ratio was primarily attributable to TOC (approximately 84 percent of the total hazard ratio). The TOC is assumed to be equivalent in toxicity to tributylphosphate, which is the most acutely toxic constituent of the organic analytes identified. Tributylphosphate was used as a surrogate because an inventory of the various chemicals that make up the TOC class is not available. The cumulative acute hazard ratio for the nearest noninvolved worker population (consisting of 335 workers located 290 m [950 ft] away) was less than 1.0 for all ERPGs, suggesting that no acute health effects would be expected.

Under bounding conditions (Table E.2.2.16), the cumulative hazard ratios for the MEI and nearest noninvolved worker (335 workers located 290 m [950 ft] away) were 2.15E+03 and 7.80E+00 for ERPG-3, respectively. These ratios were primarily attributable to:

- Uranium (approximately 47 percent of the total hazard ratio);
- Oxalate (approximately 24 percent of the total hazard ratio); and
- Mercury (approximately 13 percent of the total hazard ratio).

This exceedance of the ERPG-3 criterion for the nearest noninvolved worker population would not be expected to result in irreversible health effects or place these workers in a life-threatening situation for the following reasons.

- ERPG-3 is defined as a concentration in which a receptor can be exposed for 1 hour without irreversible health effects. Because the Hanford Site has an in-place emergency response plan designed to evacuate workers within 1 hour of an accident, workers would be expected to evacuate their location and move to an area where potential exposures would be well below ERPG-3. Therefore, this worker population would not be exposed to airborne concentrations that would be either life threatening or result in irreversible health effects.
- The estimated air concentrations of chemicals as a result of this accident were based on very conservative meteorology, which results in movement of a plume directly toward the worker population at a relatively slow rate with minimal wind dispersion. If less conservative meteorological parameters were used, wind dispersion would cause the estimated air concentrations of chemicals to be substantially less, and the ERPG-3 criterion would not be exceeded.
- Only the bounding toxic chemical evaluation exceeded ERPG-3, while the nominal evaluation was well below 1.00E+00 for ERPG-3, suggesting that the noninvolved worker population would not receive an exposure that would result in any permanent health effects.

The cumulative acute hazard ratio for the next nearest noninvolved worker population, composed of 1,500 people and located 1,780 m (5,840 ft) away, was 2.15E+00 for ERPG-2, indicating that reversible acute health effects would be expected. The cumulative acute hazard ratio for the MEI general public was 1.76E+00 for ERPG-2, indicating that reversible, acute health effects would be expected.

Corrosive/Irritant Impact from Chemical Exposure

Under nominal conditions (Table E.2.2.17), the cumulative acute hazard ratios for the MEI worker, MEI noninvolved worker and nearest noninvolved worker population (335 workers at 290 m [950 ft]) were 2.47E+01, 5.10E+02 and 1.85E+00, respectively for ERPG-3, indicating the potential for irreversible health effects that could be life threatening. These ratios were almost entirely attributable to sodium which was assumed to be equivalent to sodium hydroxide in corrosive/irritant effects.

As discussed previously, this exceedance of the ERPG-3 criterion would not be expected to result in irreversible or life threatining health effects.

For the next nearest noninvolved worker population (1,500 workers at 1,780 m [5,840 ft]), the cumulative acute hazard ratio was 1.20E+00 for ERPG-1, indicating that only mild irreversible irritant effects would be anticipated. For the MEI general public, the cumulative acute hazard ratio was less than 1.0 for all ERPGs and no acute health effects would be expected.

Under bounding conditions, the cumulative acute hazard ratios for the MEI noninvolved worker and nearest noninvolved worker population (335 workers at 290 m [950 ft]) were 7.31E+02 and 2.65E+00, respectively for ERPG-3, indicating the potential for irreversible health effects that could be life threatening. These acute hazard ratios were primarily attributable to:

- Sodium (approximately 83 percent of the total hazard ratio); and
- Calcium (approximately 10 percent of the total hazard ratio).

As discussed previously, this exceedance of the ERPG-3 criterion would not be expected to result in irreversible or life threatining health effects.

For the next nearest noninvolved worker, and MEI general public, the cumulative acute hazard ratios were 1.74E+00 and 1.42E+00 respectively for ERPG-1, indicating that only mild, transient irritant effects would be expected.

Under both nominal and bounding conditions, the probability of a seismic event is 4.34E-03.

E.11.2.3.13 Occupational Injuries and Fatalities

The number of operation person-years to support the Ex Situ Intermediate Separations alternative was estimated to be 8.37E +04 (Jacobs 1996). The total recordable injuries and illnesses, lost workday cases, and fatalities were calculated as follows:

Total Recordable Cases = (8.37 E+04 person-years) · (2.2E+00 incidences/100 person-years) = 1.84E+03

Lost Workday Cases = (8.37E +04 person-years) · (1.1E+00 incidences/100 person-years) = 9.20E+02

Fatalities = (8.37E +04 person-years) · 3.2E-03 fatalities/100 person-years) = 2.68E +00

E.11.3 POST-REMEDIATION ACCIDENT

E.11.3.1 Deflagration in Storage Tank

After 99 percent of the tank waste has been removed from each tank, the probability of a tank generating enough hydrogen to exceed the LFL is considered to be incredible.

E.11.3.2 Seismic Induced Rupture of Stabilized Tanks

As discussed in Section E.4.4.2, displacement on a fault that would increase exposure to the waste after remediation is considered incredible. The tanks would most likely crack, allowing increased infiltration to the groundwater.

E.11.4 SUMMARY OF ACCIDENTS

The potential consequences from nonradiological and nonchemical accidents that include occupational and transportation impacts are summarized in Table E.11.4.1. The LCFs associated with representative accidents for each component of the alternative are summarized in Table E.11.4.2 along with the probability of the accident. The chemical hazards associated with representative accidents for each component of the alternative are summarized in Table E.11.4.3. The chemical hazard is expressed as an exceedance of the ERPG threshold values.

Table E.11.4.1 Summary of Potential Nonradiological/Nonchemical Accident Consequences

Table E.11.4.2 Summary of Potential Radiological Accident Consequences

Table E.11.4.3 Chemical Exposures Resulting from Potential Operations and Transportation Accidents

E.12.0 NO ACTION ALTERNATIVE (CAPSULES)

The No Action alternative for Cs and Sr capsules would involve the continued operation of Waste Encapsulation and Storage Facility (WESF) for 10 years. This section analyzes potential operation and transportation risks resulting from accidents associated with this alternative. Because there would be no construction, accidents associated with construction were not analyzed.

E.12.1 TRANSPORTATION ACCIDENTS

Employee Vehicles

Personnel required to support the various activities would drive to the site in their vehicles. The total person-years to support the alternative for 10 years was calculated to be 1.00E+03 (Jacobs 1996). Each person is assumed to work 260 days of the year. The round-trip distance traveled to work from the Tri-Cities area is estimated at 140 km (87 mi) with an estimated 1.35 passengers per vehicle (DOE 1994a). The total personnel vehicle distance was therefore calculated as follows:

(1.00E+03 person-years) · (260 days/year) · (140 km/day) · (1/1.35 person) = 2.70E+07 km (1.68E+07 mi)

The expected numbers of injuries and fatalities resulting from employee vehicle accidents were calculated as follows:

Injuries = (2.70E+07 km) · (7.14E-07 injuries/km) = 1.93E+01

Fatalities = (2.70E+07 km) · (8.98E-09 fatalities/km) = 2.42E-01

E.12.2 OPERATION ACCIDENTS

The potential exists for accidents resulting from operation activities, which are discussed in Appendix B. The potential accidents were identified in the document entitled Potential Accidents for Storage and Disposition of Cesium and Strontium Capsules for the Tank Waste Remediation System-EIS (WHC 1995k). The data package provided a range of potential accidents, probability of the accidents, and the consequences of the accidents. These accidents are summarized in the Accident Screening Table (Table E.12.2.1). The dominant accident scenario analyzed in the following subsection was selected from the table.

E.12.2.1 Pool Cell Storage Accident at the Waste Encapsulation and Storage Facility

Types of potential accidents associated with pool cell storage at WESF are leaks, direct exposure, fires, mechanical impacts, and explosions. From Table E.12.2.1 , the DBA accident identified as having the highest risk would be an earthquake that would result in the combination of Accident 3.1.2 "loss of shielding in a single pool cell," and Accident 3.1.1, "strontium capsule leak."

E.12.2.1.1 Scenario and Source-Term Development for Pool Cell Storage Accident

It was postulated that the earthquake results in the roof of the building collapsing breaching 40 Sr capsules. The pool cell is also breached and all the water drained from the cell. The source-term resulting from the breached canisters for the noninvolved worker receptor as calculated in the capsule data package (WHC 1995k) would be 1.2E-01 Ci based on 8 hours exposure. The general public was calculated to be 3.5E-01 Ci based on 24 hours exposure. In addition to the source-term, the loss of the water shielding the capsules would result in high direct radiation doses to the receptors. It was assumed that all workers would die in the building from the collapsed roof.

Table E.12.2.1 Accident Screening Table for the No Action Alternative (Capsules)

E.12.2.1.2 Probability of Pool Cell Storage Accident

The initiating event is a beyond design basis earthquake with an annual exceedance frequency of 2.5E-04 per year. Based on an operation duration of 10 years, the probability of the event would be 2.5E-03.

E.12.2.1.3 Radiological Consequence of Pool Cell Storage Accident

The radiological dose to the receptors from the previous source-term was calculated by the GENII computer code (Napier et al. 1988) using the methodology previously discussed in Section E.1.1.6.

The direct radiation dose to the receptors from the accident scenario was calculated using the Monte Carlo Neutron Photon (MCNP) computer code. Because the pools are belowground, the primary source of dose rates to people outside the facility would be due to radiation scattering (often referred to as shine) from the air. The results, which are taken from the potential accident data package for the capsules (WHC 1995k), are summarized in Table E.12.2.2.

TableE.12.2.2 Dose Consequence for Pool Cell Storage Accident

E.12.2.1.4 Radiological Cancer Risk for Pool Cell Accident

To calculate the LCFs and the LCF risk (point estimate) for the receptors, a dose-to-risk conversion factor of 4.0E-04 LCF per person-rem for the noninvolved worker and MEI noninvolved worker and 5.0E-04 for the general public and MEI general public was used. The results are presented in Table E.12.2.3. Aside from the 10 workers dying from the collapsed roof, the calculations show there would be no fatal cancer.

E.12.2.1.5 Chemical Consequences for Pool Cell Accident

Chemical consequences were not evaluated in (WHC 1995k) since the small quantity of nonradiological constituents in the capsules would result in an exposure to all receptors well below the cumulative ratio of 1.0 to ERPG-1 values for toxic or corrosive/irritant chemicals.

E.12.2.2 Occupational Fatalities and Injuries

Table E.12.2.3 Latent Cancer Fatality Risk from Pool Cell Accident

The number of operation personnel was estimated at approximately 1.00E+03 person-years (Jacobs 1996). The number of injuries, illnesses, and fatalities for the 10 years of operation are calculated as follows:

Total Recordable Cases = (1.00E+03 person-years) · (2.2E+00 incidences/100 person-years) = 2.2E+01

Lost Workday Cases = (1.00E+03 person-years) · (1.1E+00 incidences/100 person-years) = 1.1E+01

Fatalities = (1.00E+03 person-years) · (3.2E-03 fatalities/100 person-years) = 3.2E-02

E.13.0 ONSITE DISPOSAL ALTERNATIVE

The Onsite Disposal alternative for Cs and Sr capsules would involve the continued operation of WESF until the disposal facility was completed. The capsules would then be removed from the basin, placed in overpack canisters, and transferred to storage for disposal where they would remain. This section analyzes potential construction, operation, and transportation risks resulting from accidents associated with this alternative.

E.13.1 CONSTRUCTION ACCIDENTS

The construction activities associated with the Onsite Disposal alternative are discussed in Appendix B of the EIS. It should be noted there are no radiological or chemical consequences associated with construction accidents. Occupational injuries, illnesses, and fatalities resulting from construction accidents are calculated in the following text.

The number of construction personnel was estimated at 2.10E+02 person-years (Jacobs 1996). The number of total recordable injuries and illnesses, lost workday cases, and fatalities for the 8 years of construction are calculated using the incidents rates from Table E.1.2.1 as follows:

Total Recordable Cases = (2.10E+02 person-years) · (9.75E+00 incidences/100 person-years) = 2.05E+01

Lost Workday Cases = (2.10E+02 person-years) · (2.45E+00 incidences/100 person-years) = 5.15E+00

Fatalities = (2.10E+02 person-years) · (3.2E-03 fatalities/100 person-years) = 6.72E-03

E.13.2 TRANSPORTATION ACCIDENTS

Transportation activities associated with this alternative include:

- Transporting construction material from offsite by truck to support WESF modifications;
- Transporting fill material from an onsite borrow site to support drywell construction;
- Transporting the overpacked capsules from WESF to drywell disposal; and
- Employees commuting to work each day.

E.13.2.1 Radiological Cancer Risk

Radiological exposures resulting from accidents during transport of the capsules to the Drywell Disposal Facility were analyzed (Green 1995), and the methodology of this analysis is discussed in Section E.1.1.6. The results of the analysis are summarized in Tables E.1 3 .2.1 and E.1 3 .2.2. The calculations show there would be no fatal cancers attributable to this exposure.

Table E.13.2.1 Integrated Radiological Impact from Accidents for the Onsite Dry Storage Alternative

Table E.13.2.2 Maximum Individual Radiological Impact from Accidents for the Onsite Dry Storage Alternative

E.13.2.2 Chemical Exposure

Because chemicals other than small amounts of common chemicals (e.g., lubricants) are required to implement in this alternative, essentially no chemical exposure would occur.

E.13.2.3 Occupational Fatalities and Injuries

Truck Transport

WESF would be modified to support overpacking operations. Construction material would be transported by truck from the Tri-Cities area 70 km (43 mi) away. This would require an estimated 200 trips.

The area of land that would be graded is 1.8E+03 m^2 (2.2E+03 yd^2). Drywells (672) would be bored with a drywell encasement placed on center in the drywell. The encasement would be backfilled with sand and covered with a sandplug after placement of the capsule in the encasement. One hundred loads of sand would be trucked from a borrow site 5 km (3 mi) away. The 672 encasement pipes would be transported by truck from the Portland or Seattle area 400 km (249 mi) away. The encasement pipe would require an estimated 14 trips.

The 1,929 capsules would be transported by truck to drywell disposal. Capsule transport would require 184 trips. Table E.13.2.3 provides a summary of the expected distance to be traveled by truck in support of the construction and capsule transport activities. The number of injuries and fatalities are calculated by multiplying the total distance traveled in each zone, shown in Table E.13.2.4 , by the appropriate unit risk factors shown in Table E.1.3.1. The expected injuries and fatalities resulting from transportation accidents associated with the alternative are summarized in Table E.13.2.5.

Table E.13.2.3 Summary of Transportation Activities for the Onsite Disposal Alternative

Table E.13.2.4 Distance Traveled in Population Zones for the Onsite Disposal Alternative

Table E.13.2.5 Injuries/Fatalities Resulting from Truck Accidents for the Onsite Disposal Alternative

Employee Vehicles

In addition to transporting materials and supplies to and from the Hanford Site by truck, site workers and other personnel required to support the various activities will be driving to the site in their vehicles.

The total person-years to support the alternative for an estimated 88 years was calculated to be 1,294 (Jacobs 1996). Each person is assumed to work 260 days of the year. The round-trip distance traveled to work from the Tri-Cities area is estimated at 140 km (87 mi) with an estimated 1.35 passengers per vehicle (DOE 1994a). The total personnel vehicle distance was therefore calculated as follows:

(1.29E+03 person-years) · (260 days/year) · (140 km/day) · (1/1.35 person) = 3.49E+07 km (2.2E+07 mi)

The expected numbers of injuries and fatalities resulting from employee vehicle accidents were calculated as follows:

Injuries = (3.49E+07 km) · (7.14E-07 injuries/km) = 2.49E+01

Fatalities = (3.49E+07 km) · (8.98E-09 fatalities/km) = 3.13E-01

The cumulative nonradiological and nontoxicological injuries and fatalities incurred as a direct result of traffic accident impacts are summarized in Table E.13.2.6. It is most likely there would be 25 injuries and no fatalities resulting from traffic accidents.

Table E.13.2.6 Cumulative Injuries and Fatalities from Traffic Impacts for the Onsite Disposal Alternative

E.13.3 OPERATION ACCIDENTS

The potential exists for accidents resulting from operation activities. The operations are discussed in Appendix B. This analysis separates and analyzes the operations according to the following modes of operation:

- Pool cell storage at WESF - Cs and Sr capsules would remain stored in water-filled basins until they are transported to drywell disposal.

- Capsule overpacking at WESF - Cs and Sr capsules would be removed from the basin and sealed in overpack canisters.
- Transport of overpacked capsules to drywell disposal.
- Storage of capsules in drywells - Cs and Sr capsules are stored in drywells for an indefinite length of time.

The potential accidents were identified in the document entitled Potential Accidents for Storage and Disposition of Cesium and Strontium Capsules for the Tank Waste Remediation System (WHC 1995k). The data package provided a range of potential accidents, probability of the accidents, and the consequences of the accidents. These accidents are summarized in the Accident Screening Table (Table E.13.3.1). The dominant accident scenarios analyzed in the following subsections were selected from the table, whose methodology was previously discussed in Section E.1.1.2.

Table E.13.3.1 Accident Screening Table for the Onsite Disposal Alternative

E.13.3.1 Pool Cell Storage Accident at the Waste Encapsulation and Storage Facility

The dominant pool cell storage accident at WESF is the earthquake previously discussed in the No Action alternative in Section E.12.2.1 and is summarized in the following.

Source-Term - The source-term presented in Section E.12.1.1 resulting from the breached canisters for the noninvolved worker receptor was 1.2E-01 Ci based on 8 hours exposure. The general public was calculated to be 3.5E-01 Ci based on 24 hours exposure. In addition to the source-term, the loss of the water shielding the capsules would result in high direct radiation doses to the receptors. It was assumed that all the workers would die in the building from the collapsed roof.

Probability - The annual exceedance frequency of the earthquake in Section E.12.2.1.2 was 2.5E-04 per year. The Onsite Disposal alternative was based on 19 years of operations; therefore, the probability was calculated to be 4.8E-03.

Radiological Consequences - The radiological consequences presented in Table E.2.2.2 are reproduced in Table E.13.3.2 .

Radiological Cancer Risk - The LCFs calculated in Section E.12.2.1.4 are the same for the Onsite Disposal alternative; however, the LCF point estimate risk is not the same due to the difference in probabilities. The LCFs and the LCF risk are calculated in Table E.13.3.3. Aside from the 10 workers dying from the collapsed roof, the calculations show there would be no fatal cancers.

Chemical Consequences - Chemical consequences presented in Section E.12.2.1.5 concluded there would be no exposure that would exceed the cumulative ratio of 1.0 to ERPG-1 values for toxic or corrosive/irritant chemicals.

Table E.13.3.2 Dose Consequence for Pool Cell Storage Accident

Table E.13.3.3 Latent Cancer Fatality Risk from Pool Cell Accident

E.13.3.2 Overpacking and Drywell Disposal Accident

Types of potential accidents associated with overpacking and drywell disposal are leaks and mechanical impacts. From Table E.13.3.1 , the DBA accident identified as having the highest risk is Accident 3.2.1, "Sr Capsule Crushed in Overpacking or Dry Storage." It was postulated that during overpacking a Sr capsule was breached when a heavy object falls on the canister.

E.13.3.2.1 Scenario and Source-Term Development for Crushed Strontium Capsule

It was assumed that the initial shock of the drop of a heavy object on the capsule would spill the entire capsule contents and loft a fraction of 1.0E-03 of the activity by free-fall. This would be resuspended for 8 hours at 4.0E-06 per hour. The source-term would be 38.5 Ci.

E.13.3.2.2 Probability of Crushed Strontium Capsule

This scenario was considered to be unlikely with a frequency range of 1.0E-02 per year to 1.0E-04 per year. For conservatism, a frequency of 1.0E-02 per year is used for calculating risk. Based on a packaging operation of 19 years, the probability was calculated to be 1.9E-01.

E.13.3.2.3 Radiological Consequence from Crushed Strontium Capsule

The radiological dose to the receptors from the accident scenario was calculated by the GENII computer code (Napier et al. 1988) using the methodology previously discussed in Section 1.1.6. The results, taken from the potential accident data package for the capsules (WHC 1995k), are summarized in Table E.13.3.4.

Table E.13.3.4 Dose Consequence from Crushed Strontium Capsule

E.13.3.2.4 Radiological Cancer Risk from Crushed Strontium Capsule

Based on a dose-to-risk conversion factor of 4.0E-04 LCF per person-rem for the worker/noninvolved worker and 5.0E-04 LCF per person-rem for the general public, the LCF risk is calculated for the receptors in Table E.13.3.5.

For the bounding scenario the calculations show there would be no fatal cancers attributable to this exposure.

The BDBA represents an unmitigated release (the HEPA filters fail). For the BDBA the calculations show all 10 workers would receive a lethal dose, there would be 1.2E+03 LCF in the noninvolved worker population, and 6.20E+02 LCFs in the general public.

E.13.3.2.5 Chemical Consequences from Crushed Strontium Capsule

Chemical consequences were not evaluated in (WHC 1995k) since the small quantity of nonradiological constituents in a capsule would result in an exposure to all receptors well below the cumulative ratio of 1.0 to ERPG-1 values for toxic corrosive/irritant chemicals.

E.13.3.3 Occupational Fatalities and Injuries

The number of operation personnel was estimated at approximately 1.08E+03 person-years (Jacobs 1996). The number of injuries, illnesses, and fatalities for the 88 years of operation are calculated as follows:

Total Recordable Cases = (1.08E+03 person-years) · (2.2E+00 incidences/100 person-years) = 2.38E+01

Lost Workday Cases = (1.08E+03 person-years) · (1.1E+00 incidences/100 person-years) = 1.19E+01

Fatalities = (1.08E+03 person-years) · (3.2E-03 fatalities/100 person-years) = 3.47E-02

TableE.13.3.5 Latent Cancer Fatality Risk from Crushed Strontium Capsule

? ? ? ? ?

E.14.0 OVERPACK AND SHIP ALTERNATIVE

The Overpack and Ship alternative for Cs and Sr capsules would involve the continued storage of the capsules in the WESF water basin with final disposal in the potential geologic repository. The capsules would not be removed from the WESF pools until a repository became available. The capsules would be removed from the pools and placed in overpacks prior to shipment. The capsules would be transported by rail to the potential geologic repository.

E.14.1 CONSTRUCTION ACCIDENTS

The construction activities associated with the Overpack and Ship alternative are discussed in Appendix B of the EIS. It should be noted there are no radiological or chemical consequences associated with construction accidents. Occupational injuries, illnesses, and fatalities resulting from construction accidents are calculated in the following text.

The number of construction personnel was estimated at 1.0E+02 person-years (Jacobs 1996). The number of total recordable injuries and illnesses, lost workday cases, and fatalities for the 8 years of construction are calculated using the incidence rates from Table E.1.2.1 of this appendix as follows:

Total Recordable Cases = (1.00E+02 person-years) · (9.75E+00 incidences/100 person-years) = 9.75E+00

Lost Workday Cases = (1.00E+02 person-years) · (2.45E+00 incidences/100 person-years) = 2.45E+00

Fatalities = (1.00E+02 person-years) · (3.2E-03 fatalities/100 person-years) = 3.20E-03

There would be an estimated 10 total recordable cases, two to three lost workday case, and no fatalities resulting from construction.

E.14.2 TRANSPORTATION ACCIDENTS

Transportation activities associated with this alternative are:

- Transporting construction material from offsite by truck to support WESF modification;
- Transporting overpacked capsules by rail from WESF the potential geologic repository; and
- Employees commuting to work each day.

E.14.2.1 Radiological Cancer Risk

Radiological exposures resulting from accidents while transporting the capsules to an offsite potential geologic repository were analyzed (Green 1995). The methodology of the analysis was previously discussed in Section E.1.1.6. The results of the analysis are summarized in Tables E.14.2.1 and E.14.2.2. The calculations show there would be no fatal cancers attributed to this exposure.

Table E.14.2.1 Integrated Radiological Impact from Accidents for the Overpack and Ship Alternative

Table E.14.2.2 Maximum Individual Radiological Impact from Accidents for the Overpack and Ship Alternative

E.14.2.2 Chemical Exposure

Only small amounts of chemicals (e.g., lubricants) would be required under this alternative so only very minor chemical exposure would be expected to occur.

E.14.2.3 Occupational Fatalities and Injuries

Table E.14.2.3 provides a summary of the expected distances to be traveled by truck and rail to support construction and capsule transport activities.

Table E.14.2.3 Summary of Transportation Activities for the Overpack and Ship Alternative

Construction Transport

There would be modifications to WESF to support overpacking operations. Construction material would be transported by truck from the Tri-Cities area 70 km (43 mi) away. This would require an estimated 200 trips.

Capsule Transport

It would require 5 rail shipments to transport the capsules to an offsite potential geologic repository 1,465 km (910 mi) away (Green 1995).

The number of injuries and fatalities are calculated by multiplying the total distance traveled in each zone, shown in Table E.14.2.4 , by the appropriate unit risk factors shown in Table E.1.3.1.

In addition to transporting materials and supplies to and from the Hanford Site, site workers and other personnel required to support the various activities would be driving to the site in their vehicles. The total person-years to support the alternative for an estimated 39 years was calculated to be 241 (Jacobs 1996). Each person is assumed to work 260 days of the year. The round-trip distance traveled to work from the Tri-Cities area is estimated at 140 km (87 mi), with an estimated 1.35 passengers per vehicle (DOE 1994a). The total personnel vehicle distance was therefore calculated as follows:

(241 person-years) · (260 days/year) · (140 km/day) · (1/1.35 person) = 6.50E+06 km (4.0E+06 mi)

Table E.14.2.4 Distance Traveled in Population Zones for the Overpack and Ship Alternative

The expected injuries and fatalities resulting from transportation accidents associated with the Overpack and Ship alternative are summarized in Table E.14.2.5.

The expected number of injuries and fatalities resulting from employee vehicle accidents were calculated as follows:

Injuries = (6.50E+06 km) · (7.14E-07 injuries/km) = 4.64E+00

Fatalities = (6.50E+06 km) · (8.98E-09 fatalities/km) = 5.84E-02

Table E.14.2.5 Injuries/Fatalities Resulting from Transportation Accidents for the Overpack and Ship Alternative

The cumulative nonradiological and nontoxicological injuries and fatalities incurred as a direct result of traffic accident impacts are summarized in Table E.14.2.6. It is mostly likely there would be 4 injuries and no fatalities resulting from traffic accidents.

Table E.14.2.6 Cumulative Injuries and Fatalities from Traffic Impacts for the Overpack and Ship Alternative

E.14.3 OPERATION ACCIDENTS

The potential exists for accidents resulting from operation activities. These operations are discussed in Appendix B. The operations are separated and analyzed according to the following modes of operation:

- Pool cell storage at WESF - Cs and Sr capsules would remain stored in water-filled basins until they are transported to drywell disposal.
- Capsule overpacking at WESF - Cs and Sr capsules would be removed from the basin and sealed in overpack canisters, and stored for shipment to a potential geologic repository.

E.14.3.1 Pool Cell Storage Accident at the Waste Encapsulation and Storage Facility

The dominant pool cell storage accident at WESF is the earthquake, which was previously discussed in the No Action alternative in Section E.12.2.1 and is summarized in the following.

Source-Term - The source-term presented in Section E.12.2.1.1 resulting from the breached canisters for the noninvolved worker receptor was 1.2E-01 Ci, based on 8 hours exposure. The general public was calculated to be 3.5E-01 Ci, based on 24 hours exposure. In addition to the source-term, the loss of water shielding the capsules would result in high direct radiation doses to the receptors. It was assumed that all of the workers would die in the building from the collapsed roof.

Probability - The annual exceedance frequency of the earthquake (Section E.12.2.1.2) was 2.5E-04 per year. The Overpack and Ship alternative was based on 19 years of operations; therefore, the probability was calculated to be 4.8E-03.

Radiological Consequences - The radiological consequences presented in Table E.2.2.2 are reproduced in Table E.14.3.1.

Table E.14.3.1 Dose Consequence for Pool Cell Storage Accident

Radiological Cancer Risk - The LCFs calculated in Section E.12.2.1.4 are the same for the Onsite Disposal alternative; however, the LCF point estimate risk is not the same due to the difference in probabilities. The LCFs and the LCF risk are calculated in TableE.14.3.2. Except for the 10 workers dying from the collapsed roof, the calculations show there would be no fatal cancers.

Table E.14.3.2 Latent Cancer Fatality Risk from Pool Cell Accident

Chemical Consequences - Chemical consequences presented in Section E.12.2.1.5 concluded there would be no exposure that would exceed the cumulative ratio of 1.0 to ERPG-1 values for toxic or corrosive/irritant chemicals.

E.14.3.2 Overpacking Accident

The dominant overpacking accident at WESF was the crushed Sr capsule previously discussed in the Onsite Disposal alternative in Section E.13.3.2 and is summarized as follows:

Source-Term - The source-term presented in Section E.13.3.2.1 resulting from the breached canisters was 38.5 Ci.

Probability - The frequency of the accident in Section E.13.3.2.2 was 1.0E-02 per year. The Overpack and Ship alternative was based on 19 years of operations; therefore, the probability was calculated to be 1.9E-01.

Radiological Consequences - The radiological consequences presented in Section E.13.3.2.3 are reproduced in Table E.14.3.3.

Radiological Cancer Risk - The LCFs calculated in Section E.13.3.2.4 are the same for the Overpack and Ship alternative and are reproduced in Table E.14.3.4.

Chemical Consequences - Chemical consequences presented in Section E.13.3.2.5 concluded there would be no exposure that would exceed the cumulative ratio of 1.0 to ERPG-1 values for toxic or corrosive/irritant chemicals.

Table E.14.3.3 Dose Consequence from Crushed Strontium Capsule

TableE.14.3.4 Latent Cancer Fatality Risk from Crushed Strontium Capsule

E.14.3.3 Occupational Injuries and Fatalities

The number of operation personnel was estimated at approximately 1.41E+02 person-years (Jacobs 1996). The number total recordable injuries and illnesses, lost workday cases, and fatalities are calculated as follows:

Total Recordable Cases = (1.41E+02 person-years) · (2.2E+00 incidences/100 person-years) = 3.10E+00

Lost Workday Cases = (1.41E+02 person-years) · (1.1E+00 incidences/100 person-years) = 1.55E+00

Fatalities = (1.41E+02 person-years) · (3.2E-03 fatalities/100 person-years) = 4.51E-03

E.15.0 VITRIFY WITH TANK WASTE ALTERNATIVE

The Vitrify With Tank Waste alternative for Cs and Sr capsules would involve the continued operation of WESF until a HLW vitrification facility was completed. The capsules would then be removed from the basin, placed in overpacks, and transferred by truck to the HLW vitrification facility where they would be cut up and blended with the HLW from the tank farms. This section analyzes potential construction, operation, and transportation risks resulting from accidents associated with this alternative.

E.15.1 CONSTRUCTION ACCIDENTS

The construction activities associated with the Vitrify with Tank Waste alternative are discussed in Appendix B of the EIS. It should be noted there are no radiological or chemical consequences associated with construction accidents. Occupational injuries, illnesses, and fatalities resulting from potential construction accidents are calculated in the following text.

The number of construction personnel was estimated at 1.00E+02 person-years (Jacobs 1996). The number of total recordable injuries and illnesses, lost workday cases, and fatalities for the 8 years of construction are calculated using the incidence rates from Table E.1.2.1 of this Appendix as follows:

Total Recordable Cases = (1.00E+02 person-years) · (9.75E+00 incidences/100 person-years) = 9.75E+00

Lost Workday Cases = (1.00E+02 person-years) · (2.45E+00 incidences/100 person-years) = 2.45E+00

Fatalities = (1.00E+02 person-years) · (3.2E-03 fatalities/100 person-years) = 3.20E-03

E.15.2 TRANSPORTATION ACCIDENTS

Transportation activities associated with this alternative are:

- Transporting construction material from offsite to modify WESF;
- Transporting the overpacked capsules from WESF to the HLW vitrification facility;
- Transporting vitrified HLW to a national HLW repository; and
- Employees commuting to work each day.

E.15.2.1 Radiological Cancer Risk

Radiological exposures resulting from accidents during transport of the capsules to the HLW vitrification facility were analyzed (Green 1995), the methodology of the analysis is discussed in Section E.6.2.1. The results of the analysis are summarized in Tables E.15.2.1 and E.15.2.2.

It is most likely there would be no fatal cancers attributable to this exposure.

TableE.15.2.1 Integrated Radiological Impact from Accidents for the Vitrify with Tank Waste Alternative

Table E.15.2.2 Maximum Individual Radiological Impact from Accidents for Vitrify with Tank Waste Alternative

The receptor dose and LCF risk resulting from the accident analysis for transporting vitrified HLW to an offsite geologic repository is presented tn Table E.15.2.3 for the integrated population and urban population. Since the capsules could be mixed and vitrified with any of the ex situ tank remediation alternatives, Table E.15.2.3 presents the

LCF Risk for each of the alternatives.

Table E.15.2.3 Radiological Impact from Transport Accident While Transporting Vitrified HLW to a National HLW Repository

E.15.2.2 Chemical Exposure

Chemicals would be transported to the Hanford Site in support of vitrifying the Cs and Sr capsules with the tank waste. An analysis was performed to identify the hazardous chemicals that could result in the largest toxicological impacts and evaluate the toxicological impacts of the bounding scenario accidents involving the highest hazard chemicals (Green 1995). A preliminary screening analysis was performed to identify the chemicals representing the highest potential toxicological hazard. The highest hazard chemicals in terms of toxicity were determined to be nitric acid and sulfuric acid. The chemical concentrations resulting from the bounding case scenario accident at 100 m (330 ft) (3.28E+02 ft) and the frequency of the accidents as postulated (Green 1995) are summarized in Table E.15.2.4.

Table E.15.2.4 Comparison of Chemical Concentrations to Corrosive/Irritant Concentration Limits for the Capsules Alternative

Table E.15.2.5 compares the respirable concentration of the postulated chemical releases to acute exposure criteria (ERPGs) discussed in Section E.1.1.7. For the MEI general public, no ERPGs would be exceeded.

Table E.15.2.5 Comparison of Exposed Chemical Concentrations to Concentration Limits for the Vitrify with Tank Waste Alternative

E.15.2.3 Occupational Fatalities and Injuries

Table E.15.2.6 provides a summary of the expected distance to be traveled by truck to support the construction and capsule transport activities.

Table E.15.2.6 Summary of Transportation Activities for the Vitrify with Tank Waste Alternative

Construction Material Transport

There would be modifications to WESF to support overpacking operations. Construction materials would be transported by truck from the Tri Cities 70 km (43 mi) and would require an estimated 200 trips.

Capsule Transport

The 1,929 capsules would be transported by truck to the HLW vitrification facility. Capsule transport would require 184 trips. The number of injuries and fatalities are calculated by multiplying the total distance traveled in each zone, shown in Table E.15.2.7 , by the appropriate unit risk factors shown in Table E.1.3.1.

Table E.15.2.7 Distance Traveled in Population Zones for the Vitrify with Tank Waste Alternative

The expected injuries and fatalities resulting from transportation accidents associated with the Vitrify With Tank Waste alternative are summarized in Table E.15.2.8.

Table E.15.2.8 Injuries and Fatalities Resulting from Truck Accidents for the Vitrify with Tank Waste Alternative

In addition to transporting materials and supplies to and from the Hanford Site by truck, site workers and other personnel required to support the various activities will be driving to the site in their vehicles. The total person-years to support the alternative was calculated to be 241 (Jacobs 1996). Each person is assumed to work 260 days of the year. The round-trip distance traveled to work from the Tri-Cities area is estimated at 140 km (87 mi) with an estimated 1.35 passengers per vehicle (DOE 1994a).

The total personnel vehicle distance was therefore calculated as follows:

(241 person-years) · (260 days/year) · (140 km/day) · (1/1.35 person) = 6.50E+06 km (4.0E+06 mi)

The expected number of injuries and fatalities resulting from employee vehicle accidents was calculated as follows:

Injuries = (6.50E+06 km) · (7.14E-07 injuries/km) = 4.66E+00

Fatalities = (6.50E+06 km) · (8.98E-09 fatalities/km) = 5.97E-02

The cumulative noncancer injuries and fatalities incurred as a direct result of traffic accident impacts are summarized in Table E.15.2.9. It is most likely there would be four injuries and no fatalities resulting from traffic accidents.

Table E.15.2.9 Cumulative Injuries and Fatalities from Traffic Impacts for the Vitrify with Tank Waste Alternative

E.15.3 OPERATION ACCIDENTS

The potential exists for accidents resulting from operation activities. These operations are discussed in Appendix B. The operations are separated and analyzed according to the following modes of operation:

- Pool cell storage at WESF - Cs and Sr capsules would remain stored in water-filled basins until they are transported to HLW vitrification facility.
- Capsule overpacking at WESF - Cs and Sr capsules would be removed from the basin and placed in overpacks.
- Vitrification preparation - Cs and Sr capsules would be cut up and blended into the HLW from tank farms.

E.15.3.1 Pool Cell Storage Accident at the Waste Encapsulation and Storage Facility

The dominant pool cell storage accident at WESF is the earthquake previously discussed in the No Action alternative in Section E.12.2.1 and is summarized as follows:

Source-Term - The source-term presented in Section E.12.2.1.1 resulting from the breached canisters for the non-involved worker receptor was 1.2E-01 Ci based on 8 hours exposure. The general public was calculated to be 3.5E-01 Ci based on 24 hours exposure. In addition to the source-term the loss of the water shielding the capsules would result in high direct radiation doses to the receptors. It was assumed that all the workers would die in the building from the collapsed roof.

Probability - The annual exceedance frequency of the earthquake in Section E.12.2.1.2 was 2.5E-04 per year. The Vitrify with Tank Waste alternative was based on 19 years of operations; therefore, the probability was calculated to be 4.8E-03.

Radiological Consequences - The radiological consequences presented in Table E.2.2.2 are reproduced in Table E.15.3.1.

TableE.15.3.1 Dose Consequence for Pool Cell Storage Accident

Radiological Cancer Risk - The LCFs calculated in Section E.12.2.1.4 are the same for the Vitrify with Tank Waste alternative; however, the LCF point estimate risk is not the same due to the difference in probabilities. The LCFs and the LCF risk are calculated in Table E.15.3.2. Aside from the 10 workers dying from the collapsed roof, the calculations show there would be no fatal cancers.

Table E.15.3.2 Latent Cancer Fatality Risk from Pool Cell Accident

Chemical Consequences - Chemical consequences presented in Section E.12.2.1.5 concluded there would be no exposure that would exceed the cumulative ratio of 1.0 to ERPG-1 values for toxic or corrosive/irritant chemicals.

E.15.3.2 Overpacking Accident

The dominant overpacking accident at WESF is the crushed Sr capsule previously discussed in the Onsite Disposal alternative in Section E.13.3.2 and is summarized as follows:

Source-Term - The source-term presented in Section E.13.3.2.1 resulting from the breached canisters was 38.5 Ci.

Probability - The frequency of the accident in Section E.13.3.2.2 was 1.0E-02 per year. The Vitrify with Tank Waste alternative was based on 19 years of operations; therefore, the probability was calculated to be 1.9E-01.

Radiological Consequences - The radiological consequences presented in Section E.13.3.2.3 are reproduced in Table E.15.3.3.

TableE.15.3.3 Dose Consequence from Crushed Strontium Capsule

Radiological Cancer Risk - The LCFs calculated in Section E.13.3.2.4 are the same for the Vitrify with Tank Waste alternative and are reproduced in Table E.15.3.4.

Table E.15.3.4 Latent Cancer Fatality Risk from Crushed Strontium Capsule

Chemical Consequences - Chemical consequences presented in Section E.13.3.2.5 concluded there would be no exposure that would exceed the cumulative ratio of 1.0 to ERPG-1 values for toxic or corrosive/irritant chemicals.

E.15.3.3 Vitrification Preparation Accident

Types of potential accidents associated with vitrification preparation include sprays, spills, leaks, and explosions. The DBA accident identified in Table E.15.3.5 as having the highest risk is Accident 3.3.3.1 "Cs ion exchange column explosion". It was postulated that a fully loaded ion exchange column over pressurizes and explodes.

Table E.15.3.5 Accident Screening Table for the Vitrify with Tank Waste Alternative

E.15.3.3.1 Scenario and Source-Term Development for Cesium Ion Exchange Column Explosion

It was postulated that after the column was loaded with Cs, undiluted nitric acid was inadvertently used to dilute the Cs from the column instead of diluted nitric acid. The nitric acid reacts with the resin giving off gas and heat. The gas over pressurizes the column and explodes. A 10 percent airborne release fraction was assumed. It is also assumed that the facility in which the ion exchange would be performed would be equipped with two stages of high-efficiency particulate filters with a LPF of 2.0E-06. The source-term was calculated to be 1.27E+06 Ci.

E.15.3.3.2 Probability of Cesium Ion Exchange Column Explosion

This was considered to be an unlikely event with a frequency range of 1.0E-02 per year to 1.0E-04 per year. For conservatism the frequency of 1.0E-02 was assumed for calculating risk. Based on 19 years of operation the probability was calculated to be 1.9E-01.

E.15.3.3.3 Radiological Consequence from Cesium Ion Exchange Column Explosion

The radiological dose to the receptors from the previous source-term was calculated by the GENII computer program using the methodology previously discussed in Section E.1.1.6. The results are summarized in Table E.15.3.6 (WHC 1995k).

Table E.15.3.6 Dose Consequence from Cesium Ion Exchange Column Explosion

E.15.3.3.4 Radiological Cancer Risk from Cesium Ion Exchange Column Explosion

Based on a dose-to-risk conversion factor of 4.0E-04 LCF per person-rem for the worker and noninvolved worker and 5.0E-04 LCF per person-rem for the general public, the LCF risk is calculated for the receptors in Table E.15.3.7.

TableE.15.3.7 Latent Cancer Fatality Risk from Cesium Ion Exchange Column Explosion

The calculations show there would be no fatal cancers attributable to this exposure. Because the accident would occur in a canyon and the release would be from the stack, the workers would not receive a dose.

E.15.3.3.5 Chemical Consequences from Cesium Ion Exchange Column Explosion

Chemical exposures resulting from accidents at the vitrification facility are addressed in the Ex Situ Intermediate Separations alternative in Section E.6.

E.15.3.4 Occupational Fatalities and Injuries

The number of operation personnel was estimated at approximately 1.41E+02 person-years (Jacobs 1996). The number of total recordable injuries and illnesses, lost workday cases, and fatalities are calculated as follows:

Total Recordable Cases = (1.41E+02 person-years) · (2.2E+00 incidences/100 person-years) = 3.10E+00

Lost Workday Cases = (1.41E+02 person-years) · (1.1E+00 incidences/per 100 person-years) = 1.55E+00

Fatalities = (1.41E+02 person-years) · (3.2E-03 fatalities/100 person-years) = 4.51E-03

E.16.0 VITRIFIED HLW TRANSPORT TO THE POTENTIAL GEOLOGIC REPOSITORY

Under the ex situ treatment alternatives the HLW streams would be vitrified or calcined and eventually shipped to a geologic repository assumed to be located 2,140 km (1,330 mi) offsite by a dedicated train of 10 railcars per train. The nonradiological and radiological transportation impacts associated with this activity are evaluated in this section.

E.16.1 NONRADIOLOGICAL TRANSPORTATION IMPACTS

The nonradiololgical impacts are injuries and fatalities resulting from rail accidents. The number of injuries and fatalities were calculated by multiplying the total distance traveled in each zone shown in Table E.16.1.1 by the appropriate unit risk factors shown in Table E.1.3.1. The expected injuries and fatalities resulting from transportation accidents associated with each ex situ stabilization alternative are summarized in Table E.16.1.2.

Table E.16.1.1 Distance Traveled in Population Zones

Table E.16.1.2 Injuries and Fatalities from Rail Transportation Accidents

E.16.2 RADIOLOGICAL CONSEQUENCES

Radiological exposures resulting from routine exposures and accidents while the waste is in transit were analyzed using RADTRAN 4 (Neuhauser-Kanipe 1992).

Travel fractions and population densities for the offsite rail shipments were determined using a computer code (Peterson 1985, Green 1995). For shipments to the geologic repository in the western United States, the following travel fractions were used:

- Rural population zones - The population density was assumed to be 3.4 persons/km^2 (8.8 persons/mi^2). The fraction of the route spent in rural zones was 0.936 (i.e., nearly 94 percent of the route would be rural);
- Suburban population zone - The population density was assumed to be 406 person/km^2 (1,051 persons/mi^2). The fraction of the route spent in suburban zones was 0.055; and
- Urban population zone - The population density was assumed to be 1,959 persons/km^2 (5,074 persons/mi^2). The fraction of the route spent in urban zones was 0.009.

For routine risk, the key variable in the code was the dose rate from the vehicle package. The radioactive shipments in this analysis were assumed to be less than the regulatory maximum dose rate of 10 mrem per hour at 1 m (3.3 FT) (Jacobs 1996).

For accidents, the population doses calculated by RADTRAN 4 were dependent on the accident probability, release quantities, atmospheric dispersion parameters, population distribution parameters, human uptake, and dosimetry models (Jacobs 1996).

The routine exposures were addressed as onsite population LCF risk and offsite population LCF risk. The analysis addressed radiological accident impacts as both integrated population LCF risk (i.e., accident frequencies times consequences integrated over the entire shipping campaign) and urban population LCF risk. The routine and accident LCF risks resulting from transporting vitrified or calcined HLW to a potential geologic repository are presented in Table E.16.2.1 for each of the ex situ treatment alternatives.

A main uncertainty associated with calculating the radiological doses resulting from transporting HLW to a potential geologic repository is the location of the repository. The analysis was based on the assumption that the waste would be transported to Yucca Mountain, should that site be shown to be acceptable and approved as a potential geologic repository. If Yucca Mountain should not be approved, the LCF risks could increase or decrease depending on the distance and population pathways of the alternative site.

Other uncertainties that would impact the LCF risk is the percent of the waste by weight that could be mixed with the glass matrix. To demonstrate these uncertainties, a sample scenario for the Ex Situ Intermediate Separations alternative is presented in Table E.16.2.2. The baseline analysis used in the EIS assumed a 20 weight percent waste loading. A range from the base line from as little as 15 weight percent to as much as 40 weight percent are used in the uncertainty evaluation (Jacobs 1996).

Table E.16.2.1 LCF Risk from Routine and Accident Radiological Exposures While Shipping Vitrified or Calcined HLW By Rail To A Proposed Geologic Repository

Table E.16.2.2 Uncertainty Evaluation for HLW Glass Transport - Ex Situ Intermediate Separations Alternative

F.4.0 FLOW AND TRANSPORT MODEL

The vadose zone and groundwater modeling effort used VAM2D to predict contaminant migration through the vadose zone and groundwater. VAM2D has been previously used for flow and transport assessments at the Hanford Site. The model formulation used in the code is a descendant of that used in the SATURN code presented by Huyakorn et al. (Huyakorn et al. 1984, 1985) and was developed by HydroGeoLogic Inc. (Huyakorn et al. 1991).

The approach used for this modeling effort relies as much as possible on extensive previous work completed at the Hanford Site (e.g., hydrogeological investigations and modeling studies). Understanding and being able to predict changes in the hydraulic head of the unconfined aquifer is in an advanced stage at the Hanford Site. However, contaminant transport in the unconfined aquifer and flow and contaminant transport in the vadose zone are still in relatively early stages of understanding and development. The modeling approach was as follows:

- A combined groundwater flow and transport code (VAM2D) was used.
- Hydrogeologic and contaminant transport parameters from previous studies, including Wood et al. (Wood et al. 1995), Kincaid et al. (Kincaid et al. 1993), and Wurstner and Devary (Wurstner-Devary 1993) were used in this modeling effort.
- The VAM2D flow model of the unconfined aquifer at the Hanford Site was developed based on a previously published Sitewide calibrated groundwater flow model developed with the CFEST code (Wurstner-Devary 1993). The VAM2D flow model of the unconfined aquifer was then benchmarked against these results.

Details of the approach used to test the model are provided in the following sections.

F.4.1 FEATURES OF THE VAM2D FLOW AND TRANSPORT CODE

VAM2D is a 2-D, finite element model developed for simulating saturated and unsaturated flow and transport. Using a single model code for both vadose zone and groundwater modeling simplified the combined modeling effort. VAM2D is capable of performing flow and transport simulations in vertical cross-sections as well as horizontal orientations.

The capabilities of VAM2D applicable to the TWRS EIS modeling effort include the following:

- Simulates flow and transport in saturated and unsaturated zones;
- Solves flow and transport simultaneously or sequentially;
- Accommodates a wide range of field conditions;
- Computes hysteretic effects on flow because of wetting and drying cycles; and
- Computes the effects of variable anisotropic hydraulic conductivities on flow in stratified media.

F.4.2 LIMITATIONS OF THE TRANSPORT MODEL

Limitations of VAM2D specified in the user's manual (Huyakorn et al. 1991) include the following:

- Does not simulate three-dimensional flow. However, a 2-D analysis is appropriate for the site in that there is a lower confirming bed in the Ringold Formation, and sufficient data to develop a three-dimensional flow and transport model may not be available;
- In performing variably saturated flow, the code handles only single-phase flow (i.e., water) and ignores the flow of a second phase (i.e., air or other nonaqueous phase). This is not a concern as aqueous phase liquids are not reported in site inventory;
- The code does not address kinetic sorption effects and/or reversible chemical reactions; and
- The groundwater flow portion of the model was executed for steady-state conditions. This did not allow simulation of the decay of the groundwater mounds associated with waste disposal activities.

F.4.3 RELIABILITY TESTING OF CALCULATED RESULTS

Several tests may be performed to demonstrate a model's ability to reasonably predict flow and contaminant transport. These include:

- Verification - Comparing the numerical solutions generated by the model with one or more analytical solution or with other solutions.
- Benchmarking - Testing the model solution against the solution of other models for the same problem.
- Calibration - Establishing that the model can reproduce field-measured conditions.
- Validation - Comparing model results with detailed field data.
- Parameter Sensitivity - Quantifying the uncertainty in the calibrated model caused by uncertainty in the estimates of the parameters used.

The following sections describe reliability testing performed on VAM2D for the Hanford Site.

F.4.3.1 Verification

A number of tests were performed to ensure reliability of the code on the computer platform used for the modeling effort (IBM RS/6000 workstation) and to compare results with known analytical solutions. These included the following:

- Initially verifying the model against sample problem 1 in the VAM2D User's Manual;
- Verifying results for saturated flow against an analytical solution (Dupuit solution) (Fetter 1994); and
- Verifying results for saturated transport against an analytical solution (Domenico solution [Domenico 1985]).

The sample problem results matched the results published in the VAM2D User's Manual for head, saturated value, and x-velocity. Y-velocity values differed slightly, however the differences were less than 2.0E-13. The results published in the user's manual were for VAM2D Version 5.2; Version 5.3 was used for this modeling effort.

For the flow problem to be solved with the Dupuit solution, a simple model was constructed and solved for unconfined flow with fixed head boundaries at each end and fixed across a transect. The analytical solution was calculated for several points and compared to the model results. VAM2D model results very closely matched the Dupuit solution. Results calculated by VAM2D compared to the analytical solution are provided as follows.

Distance from Left Boundry	Head Calculated by VAM2D	Head Calculated by Dupuit Solutions
12.5 m	5.844 m	5.846 m
37.5 m	4.90 m	4.981 m

For the transport problem to be solved with the Domenico solution, a simple 2-D model was constructed and solved for transient transport. A contaminant was input at one grid node and a transient model run was performed to predict contaminant concentrations for several node points at a specified point in time (300,000 days). Concentrations based on the Domenico solution were calculated for several points and compared to the model results. VAM2D model results very closely matched the Domenico solution. Results calculated by VAM2D compared to the analytical solution are provided as follows.

Grid Location		Concentration Calculated	Concentration Calculated
Delta X	Delta Y	by VAM2D	by Domenico Solution
10 m	0 m	453.3 mg/L	455.71mg/L
20 m	5 m	85.08 mg/L	83.15 mg/L

30 m	0 m	270.5 mg/L	273.13.73 mg/L71mg/L
40 m	10 m	14.60 mg/L	

F.4.3.2 Benchmarking

The groundwater flow model effort was developed and benchmarked as follows:

- Unconfined aquifer flow parameters and boundary conditions used to set up the VAM2D model were developed from published groundwater flow modeling work using CFEST (Wurstner-Devary 1993). This effort has undergone verification, calibration, and quasi-validation efforts, which were initiated in the mid-1960's.
- VAM2D predictions of hydraulic head were compared to these published CFEST results (Wurstner-Devary 1993). Basic differences in the model input requirements and the grid used required minor adjustments, primarily to boundary discretization, to obtain a closer match.

Figure F.4.3.1 shows both the published results from prior model development and the hydraulic heads calculated with the VAM2D model. As expected, this figure indicates good agreement between the VAM2D results and the previously published results.

F.4.3.3 Calibration

Calibration of a groundwater model consists of comparing its results to an independent standard. Changing flow conditions at the Hanford Site make an absolute calibration infeasible. However, a qualitative calibration can be performed. This qualitative calibration begins by examining the geometry of a tritium plume that is present on the Hanford Site and estimating tritium travel times from the 200 East Area to the Columbia River. Contaminants originating from the 200 East Area are estimated to take approximately 20 to 25 years to reach the Columbia River. The estimated travel time is based on site operations beginning in the 1940's and detection of contaminants in springs and groundwater in the 1970's.

In this qualitative calibration effort, the VAM2D model was used to simulate a contaminant concentration of 200,000 mg/L source originating from B Pond in the 200 East Area. Discharge fluid fluxes were based on 1979 data, and the transient transport simulation was based on the steady-state field (also based on 1979 data). Figure F.4.3.2 provides estimates of tritium levels observed in groundwater based on 1977 environmental monitoring (Meyers 1978). Figure F.4.3.3 provides the 300 mg/L isoconcentration lines for tritium at 10, 20, and 30 years, assuming this constant discharge rate. Figure F.4.3.3 demonstrates that the travel times calculated by VAM2D correspond well with the assumed 20- to 25-year travel time. Additionally, the plume geometry for the tritium plume originating from the 200 East Area (Figure F.4.3.2) is similar to the predicted plume geometry (Figure F.4.3.3). An exact match between these two plumes should be not expected because discharge amounts varied substantially over time, and the observed tritium plume (Figure F.4.3.2) was created by multiple sources. However, similarities between the two plume geometries indicate that the VAM2D results are reasonable.

F.4.3.4 Validation

Validating a groundwater model consists of comparing model results with detailed field data. However, rigorous validation requires accurate historic data on effluent discharges as a function of time.

Although data are available on flow and transport within the unconfined aquifer, the data set is not sufficient to perform a detailed model validation. Flow conditions have changed dramatically since the early 1940's, primarily as the result of changes in wastewater discharges. Historic records of effluent amounts and water quality have not been maintained since that time in sufficient detail to perform a rigorous validation of flow and transport in the unconfined aquifer.

F.4.3.5 Parameter Sensitivity

Parameter sensitivity was investigated for the following areas:

- The effect of higher glass surface areas for the In Situ Vitrification alternative;
- The effect of changing the performance period of the Hanford Barrier from 1,000 to 500 years;
- The effect of the decay of the potentiometric head resulting from groundwater mounding due to discharge to the Hanford Site ponds;
- The effect of variations in filtration rate; and
- The effect of variations in distribution coefficient (K_d).

The approach and conclusion from these investigations are provided in Volume Five, Appendix K.

F.4.4 MODELING ASSUMPTIONS AND UNCERTAINTIES

This appendix provides the basis of potential groundwater impacts associated with each of the TWRS alternatives. Developing the groundwater assessments provided in this appendix required several assumptions to uncertainties of some of the data. The major assumptions and uncertainties are related to either the natural system (i.e., an understanding and ability to assign vadose zone and aquifer parameter values) or uncertainties inherent to the assessment approach.

The most important assumptions and uncertainties are as follows:

- The rates of infiltration into natural ground and through a cap;
- Distribution coefficient (K_d) of contaminants;
- Uncertainty in future groundwater flow direction due to decay of groundwater mounds onsite;
- Uncertainty in future groundwater flow direction and vadose zone thickness due to climate change;
- Uncertainty in vadose zone transport due to use of one-dimensional flow and transport simulation; and
- Uncertainty due to calculation of releases during retrieval.

The basis for these assumptions and their potential impact on the alternatives is provided in Volume Five, Appendix K.

F.4.5 CONCEPTUAL GROUNDWATER CUMULATIVE IMPACTS

This section addresses potential cumulative groundwater impacts of other past and projected future waste disposal activities. The activities that may have a cumulative impact on the TWRS alternatives are as follows :

- Past-practice waste disposed of to the ground as liquid;
- Past leaks from waste tanks;
- Past-practice waste disposed of to the ground as solid;
- Solid low-level radioactive waste to be disposed of in the Environmental Restoration Disposal Facility (ERDF);
- Solid low-level radioactive waste to be disposed of in the 200 West Area burial grounds; and
- Solid low-level radioactive waste to be disposed of in the US Ecology burial grounds.

These activities result in both near-term and long-term groundwater impacts. The near-term impacts are in response to past-practice liquid waste disposal to the ground. Large volumes, over 1.29E+12 L (3.40E+11 gal) in the 200 Areas, containing radionuclides and hazardous chemicals have been discharged to the ground surface or subsurface since 1944 (Wodrich 1991). Long-term groundwater impacts are associated with 1) leaching of solid waste disposed of to the ground in the 200 Areas and on the Central Plateau (Wood et al. 1995), and with 2) the relatively low-volume leaks from the waste tanks, as compared with volumes discharged to cribs and ponds. It is assumed that all of these disposal activities, except for the past-practice liquid disposal, would have some cumulative impact with respect to the TWRS activities. Quantitative information, such as would be developed for a performance assessment, on the fate of current contaminant plumes resulting from past-practice liquid waste disposal is not available; however, the following discussion suggests these contaminants will not interact with groundwater contaminant plumes associated with the TWRS alternatives.

Potential cumulative impacts with respect to contaminants C-14, I-129, Tc-99, and uranium are provided in the following sections for each of the solid waste disposal facilities. These contaminants were chosen for comparison because they have high mobility in the Hanford vadose zone and groundwater, have been routinely monitored in the groundwater, and have been identified as contributing much of the tank waste-related risk.

F.4.5.1 Past-Practice Liquid Waste Disposal

Liquid waste disposal has resulted in extensive groundwater contamination in the 200 Areas as well as downgradient toward the Columbia River. Information on specific contaminants disposed of to ground surface or subsurface is limited to only a few key constituents including nitrate and radionuclides with half-lives greater than 10 years and in quantities large enough to be of concern in waste disposal and cleanup (Wodrich 1991). These radionuclides are Sr-90/Y-90, Cs-137, Tc-99, I-129, uranium, Am-241, and plutonium. Table F.4.5.1 provides a comparison of the inventories estimated for the past-practice liquid and solid waste disposal, past waste tank leaks, and TWRS tank waste. Quantitative estimates of contaminant concentration in groundwater with an acceptable degree of uncertainty from past-practice liquid waste disposal activities are not possible using available information. Key information that is not available includes definition of the multiple source terms (e.g., waste volume, contaminant concentration, release duration) and residual waste remaining in the vadose zone. A semi-quantitative approach coupled with some qualitative assumptions is used because of these limitations.

The past-practice liquid waste disposal impacts on groundwater are believed to be ongoing and would be greatly reduced by the time the TWRS alternatives would potentially impact groundwater. Thus, they are considered near-term impacts. These conclusions are based on several assumptions and on observations of groundwater contaminant concentration trends discussed later in this section. The assumptions are as follows:

- Present groundwater contaminants, concentration levels, and distribution in the 200 Areas and downgradient are a result of the past-practice liquid disposal in the 200 Areas.
- All liquid waste disposal to the ground at previously used waste disposal facilities (e.g., cribs, trenches, drains, and reverse wells) has been stopped or will be stopped by the year 2000.
- There will be no new ground disposal of radioactive or hazardous chemical-containing liquids, except for tritium.
- The remediation alternative for the past-practice liquid waste disposal sites will be installation of caps by the year 2005.
- Less mobile contaminants in the past-practice liquid waste may contribute to the cumulative impact but are not considered at this time.

Given these assumptions, the present concentrations of highly mobile contaminants in groundwater such as tritium, Tc-99, I-129, nitrate, and to a lesser extent, uranium currently would be experiencing a large reduction in concentration that would continue for less than 10 years, followed by many years where the contaminant concentration in groundwater diminishes at a much slower rate. Change in uranium concentrations in well 299-W19-18 is an example of this process. This well is located in the 200 West Area adjacent to the inactive 216-U-1 and 216-U-2 cribs. The uranium concentration in this well has reduced at a uniform rate of approximately 3,000 µg/L for a 2 to 3-year period since remediation of the cribs in 1988 (Woodruff-Hanf 1993). By the end of 1992, the uranium concentration in this well was approximately 750 µg/L and the rate of reduction had dropped to approximately 80 ug/L/yr. The rate of concentration reduction is expected to continue to decline but at a very slow rate such that the uranium concentration at this well would appear to become constant at some low level. This level is not known and is assumed to be inconsequential by the time contaminants from the tanks arrive at the groundwater. This early reduction in concentration also is observed for tritium in observation well 699-24-33 (Woodruff-Hanf 1993).

In the performance assessment for the low-level waste burial grounds in the 200 West Area (Wood et al. 1995), it is concluded that mixing of the present day plume with that from the burial grounds is unlikely. These burial grounds include disposal sites with and without caps, thus times to peak groundwater contaminant concentrations range from approximately 125 to 1,000 years from present. The performance assessment presents the following discussion to support this conclusion. First, the particle velocity in the unconfined aquifer, on the order of 10 m/yr, would result in the migration of the present plume a few hundred meters over a few decades (Wood et al. 1995). Secondly, additional plume generation is unlikely because liquid discharge nearly has ceased, and it is likely that only very small quantities of the mobile radionuclides such as Tc-99, C-14, and I-129 remain in the present soil column. Other less mobile radionuclides are present in the soil column. They are believed to be short-lived (Wood et al. 1995) and would decay to inconsequential quantities before reaching the unconfined aquifer.

Of all the TWRS alternatives, the No Action and Long-Term Management alternatives have the earliest potential groundwater impact. First arrival of contaminants to the groundwater has been estimated to occur at about 140 years for these alternatives. Estimated first arrival of contaminants to groundwater for the other alternatives ranges from approximately 1,070 years for the ex situ alternatives to 2,330 years for the in situ alternatives. Cumulative impacts with respect to past-practice liquid disposal likely would be very low for the ex situ and in situ alternatives and, with a larger degree of uncertainty, is assumed to be very low for the No Action and Long-Term Management alternatives.

F.4.5.2 Past Leaks From the Single-Shell Tanks

Liquid waste from past tank leaks has resulted in vadose zone contamination beneath the leaking tanks and may be impacting the groundwater in the vicinity of the tanks. Potential groundwater impacts are currently being investigated as part of Resource Conservation and Recovery Act (RCRA) Groundwater Assessments for the T Farm Waste Management Area and will be ongoing soon for the S-SX and B-BX-BY Waste Management Areas.

Past SST tank leaks are considered to result in long-term groundwater impacts (compared to impacts from liquid waste disposal discussed in Section F.4.5.1) because the leak volume was, for the most part, insufficient to immediately flush the contaminants all the way through the vadose zone and into the underlying groundwater. Under current conditions (e.g., no cap over the tanks), impacts to the underlying groundwater are expected to occur over a period similar to that predicted for the No Action alternative, which is approximately 300 years. Groundwater impacts from past tank leaks would be expected to begin soon and may already be occurring because contaminants from the leaks are likely distributed vertically in the vadose zone from the tank bottoms to near the water table. A bounding approach is used to the extent practicable to estimate potential impacts from past waste tank leaks. The leak volume is taken as the upper range of the cumulative leak volume as provided in the inventory and surveillance reports (Hanlon 1996). The release to the groundwater is assumed to be analogous to release to the groundwater in the No Action alternative. Provided in the following discussion are the estimated leak volume, radioisotope content of the leaks, and the potential impact of the leaks on groundwater.

Leak monitoring is ongoing for the 177 waste tanks, and reports on waste inventory and surveillance are released monthly and quarterly. The report for the month ending February 29, 1996 (Hanlon 1996) indicates that 67 of the 149 SSTs are assumed leakers. There are no reported leaks from the 28 DSTs. The tank identification number, date tank was declared leaker, estimated leak volume, estimated activity of leak, and date the tank was stabilized are provided in Table F.4.5.2. The range of leak volume is from approximately 1,300 L (350 gal) from tank 241-C-204 in the 200 East Area to 436,000 L (115,000 gal) from tank 241-T-106 in the 200 West Area. Total leak volume from all 67 assumed leakers ranges from 2.30E+06 to 3.4E+06 L (600,000 to 900,000 gal). Interim stabilization has been completed on all but five assumed leaking tanks.

The monthly tank waste and surveillance reports (Hanlon 1996) provide a estimated range of Cs-137 associated with the waste tank leaks. However, quantitative estimates of radioisotopes such as Tc-99, C-14, I-129, and U-238 in the liquids that leaked from the waste tanks are not available. The activities of Tc-99 and uranium (assumed to be U-238) isotopes that would have been released with the tank leaks were estimated based on the total and isotopic activity of liquid waste disposal in the 200 Areas (including waste tank leaks) (Wodrich 1991). These estimates, provided in Table F.4.5.2, include an upward adjustment to account for the upper bound of leak volume of 3.4E+06 L (900,000 gal). (Hanlon 1996). The amount or activity of nitrate and C-14, respectively, was estimated based on the 3.4E+06 L (900,000 gal) cumulative leak volume and the concentration of each contaminant in the tanks as shown on Table F.2.2.14. Nitrate is assumed to have a concentration of 3.6E+02 g/L in all the tanks. The concentration of C-14 varies from tank to tank, therefore, the maximum concentration in any one SST source area was used, which was 6.74E-05 g/L in source area 2ESS. The estimated past leak quantities for these constituents are provided in Table F.4.5.2.

The potential impacts to groundwater are provided for waste tank leaks in terms of maximum potential concentration of four critical isotopes. These estimated values are provided in Table F.4.5.3. The estimated maximum concentrations of the selected contaminants in groundwater range from approximately 1 percent (for nitrate) to 25 percent (for U-238) of the maximum predicted values for the No Action alternative.

F.4.5.3 Past-Practice Solid Waste Disposal

Quantitative estimates of contaminant concentration in groundwater with an acceptable degree of uncertainty from past-practice solid waste disposal activities is not possible with the present available information. As with past-practice liquid waste disposal, key information not available includes definition of the multiple source terms (e.g., waste volume, contaminant concentration, release duration). A semi-quantitative approach is used because of these limitations.

The approach is based on the premise that the potential impacts from the In Situ Fill and Cap alternative can be used as an analog for estimating impacts from past-practice solid waste disposal. This estimate is conservative given the following major assumptions.

- The remediation alternative for the past-practice solid waste disposal sites will be installation of caps by the year 2005.
- The inventory of past-practice solid waste is in proportion to the distribution of waste in the tanks.

Contaminants from past-practice solid waste disposal would be expected to reach the groundwater at approximately the same time as contaminants from the In Situ Fill and Cap alternative, given the previous assumptions. Based on the ratio of estimated past-practice solid waste disposed to waste in tanks for C-14 and uranium (Table F.4.5.2), a factor of 1.2 is used to adjust the calculated groundwater concentrations upward from the In Situ Fill and Cap alternative. This is a semi-quantitative approximation of the potential impacts of the past-practice solid waste disposal. Table F.4.5.3 provides the potential maximum groundwater concentrations for Tc-99, I-129, C-14, and uranium. Maximum groundwater impacts of the past-practice solid waste disposal activities would occur at approximately 5,000 years based on the In Situ Fill and Cap alternative analog.

F.4.5.4 Solid Low-Level Radioactive Waste Disposal in the Environmental Restoration Disposal Facility

The proposed ERDF is a deep-lined trench disposal facility for the waste generated by the Comprehensive Environmental Response, Compensation, and Liability Act of 1980 cleanup activities. The ERDF will be located adjacent to the southwest corner of the 200 West Area. The waste will be disposed of primarily in bulk noncontainerized form and is anticipated to consist primarily of contaminated soils and concrete rubble (Wood et al. 1995a). There are currently two principal documents that provide calculated groundwater dose information: the Remedial Investigation and Feasibility Report for the Environmental Restoration Disposal Facility (DOE 1994h) and the Environmental Restoration Disposal Facility Performance Assessment (Wood et al. 1995a). The performance assessment (PA) was used herein as the basis for potential ERDF inventory and groundwater contaminant concentrations because the approach taken in the PA is similar to that used to calculate groundwater impacts from the TWRS waste tanks.

The projected ERDF inventory for Tc-99, I-129, C-14, and uranium is provided in Table F.4.5.2 (Wood et al. 1995a). The PA provides calculated groundwater drinking dose estimates for these radionuclides based on consumption of 730 L/yr (193 gal/yr). The maximum groundwater concentration for these radionuclides is calculated from the maximum dose using the drinking water consumption rate assumed in the PA and the DOE internal dose factor (Wood et al. 1995a).

Using Tc-99 as an example, the maximum groundwater concentration is calculated as follows. The reported maximum drinking water dose is 0.007 mrem/yr (Wood et al. 1995a) and the DOE internal dose factor for Tc-99 is 1.3E-06 mrem/pCi (Wood et al. 1995a). The maximum groundwater concentration of Tc-99 is calculated by dividing the reported maximum dose of 0.007 mrem/yr by the consumption rate of 730 L/yr (193 gal/yr) and the internal dose factor of 1.3E-06 mrem/pCi. This results in a maximum Tc-99 concentration in groundwater of 7.38 pCi/L. This maximum concentration would occur at approximately 1,500 years from present, assuming a K of zero and d

infiltration rate of 0.5 cm/yr (0.2 in./yr) (Wood et al. 1995a). Calculated maximum groundwater concentrations for Tc-99, I-129, C-14, and uranium are provided in Table F.4.5.3.

F.4.5.5 Solid Low-Level Radioactive Waste Disposal in the 200 West Burial Grounds

The 200 West low-level waste burial grounds consist of shallow (5 to 10 m deep [16 to 33 ft]), unlined trenches of variable widths (3 to 10 m wide [10 to 33 ft]), and lengths (50 to 100 m long [160 to 330 ft]). Potential groundwater impacts have been calculated in the Performance Assessment for the Disposal of Low-Level Waste in the 200 West Area Burial Grounds (Wood et al. 1995). This performance assessment examines the potential groundwater impacts from disposal of waste in two different facility types. The first, called a Category 1 waste facility, is assumed to have no functional barriers (e.g., cap) and is intended to contain very low concentrations of radionuclides. The other facility is called a Category 3 waste facility and is assumed to have a cap that controls infiltration to the same degree as the natural soil and vegetative system (Wood et al. 1995). Radionuclide inventory for each waste category is provided in Table F.4.5.2.

The maximum groundwater contaminant concentration for Tc-99, I-129, C-14, and uranium was calculated as described in Section F.4.5.3 and is provided in Table F.4.5.3.

F.4.5.6 Solid Low-Level Radioactive Waste Disposal in the US Ecology Burial Grounds

The US Ecology Burial Grounds is a commercial low-level waste disposal facility located on the Central Plateau just southwest of the 200 East Area and approximately 4 km (2.5 mi) east of the 200 West Area. Radionuclide inventory and maximum groundwater concentrations for Tc-99, I-129, C-14, and uranium were estimated for the US Ecology site at closure (Jacobs 1996). These values are based on preliminary estimates of future solid radioactive waste emplacement at the site. The estimates assume closure of the facility in about the year 2063. The inventory and maximum groundwater concentrations are provided in Tables F.4.5.2. and F.4.5.3, respectively.

F.4.6 Groundwater Impacts for Nominal Case

The preparation of the groundwater impacts assessment required numerous assumptions concerning not only the subsurface conditions that affect fate and transport through the vadose zone and unconfined aquifer but also the contents of the waste tanks and the release of waste during remediation. Bounding assumptions were used that would result in calculations of impacts than would be conservative compared to impact results based on average or nominal assumptions. This section provides calculated groundwater impacts for nominal estimates of waste tank releases for a scenario modified from the Ex Situ Intermediate Separations alternative. All other approaches and assumptions relative to fate and transport in the vadose zone and groundwater are the same as were used for calculating the groundwater impacts for the Ex Situ Intermediate Separation alternative summarized in Section F.3.5.

F.4.6.1 Nominal Case Source Term

The source term for this scenario is a result of releases from SSTs during waste retrieval, releases from the residuals in SSTs and DSTs, and releases from the LAW vaults. Only the long-term mobile risk contributing contaminants are considered for this scenario. These contaminants are I-129, C-14, Tc-99, and U-238. The grouping of these contaminants is the same for the base case Ex Situ Intermediate alternative scenario except for Np-237. The base-case Ex Situ Intermediate Separations alternative includes Np-237 with the above group of long-term mobile risk contributing contaminants. There is a large uncertainty surrounding the mobility of Np-237 in the Hanford Site vadose zone and unconfined aquifer and for the bounding impact analyses, it was conservatively placed in K_d group 1 (K_d = 0), which means that Np-237 would move at the same rate as the water in the vadose zone and underlying aquifer. For the nominal case scenario, Np-237 is assumed to have a K_d of 1 mL/g. In the following, a discussion of each of the three potential sources for the nominal case scenario is provided.

Released During Waste Retrieval

As with the bounding scenario for the Ex Situ Intermediate Separations alternative, retrieval releases only occur from the SSTs. The DSTs are assumed to have no releases during retrieval. Retrieval occurs over a 15-year period and the work is assumed to be ongoing at all eight of the source areas during this period. The infiltration scenario is the same as that assumed for the Ex Situ Intermediate Separations alternative, where it would decrease to 0.5 cm/yr (1.36E-05 m/day) for a 29-year period (15-year period of waste retrieval followed by a construction period or 14-years) from 5.0 cm/yr (1.36E-04 m/day). Infiltration through the Hanford Barrier at the end of construction is assumed to be 0.05 cm/yr (1.36E-06 m/day) for a 1,000-year period. It is assumed to double to 0.10 cm/yr (2.74E-06 m/day) after the 1,000-year period and remain at that level for the remainder of the period of interest.

The assumed release volume of 15,000 L (4,000 gal) per SST is retained for this scenario. For the nominal case, the contaminant concentration in the retrieval releases is two-thirds of the concentrations assumed for the Ex Situ Intermediate Separations alternative. The contaminants released during retrieval, their estimated mass and concentrations are provided in Tables F.4.6.1 and F.4.6.2. For this analysis, only the long-term risk contributors Tc-99, I-129, C-14, and U-238 are considered.

Releases from Waste Tank Residuals

The bounding scenario for the Ex Situ Intermediate Separations alternative incorporates an assumption that 1 percent of initial total tank waste remains after retrieval as a residual. This assumption does not account for recovery of the more soluble constituents during hydraulic retrieval. For the nominal case scenario, mobile soluble constituents in the residual inventory for the base case Ex Situ Intermediate Separations alternative are reduced, based on sludge wash factors reported in WHC-EP-0616. The residual inventory, concentration, and duration of release for the long-term risk contributors are provided in Table F.4.6.3, F.4.6.4, and F.4.6.5, respectively.

Releases from the LAW vaults

The releases from the LAW vaults for this scenario have not been modified from the bounding Ex Situ Intermediate Separations alternative because their contribution to overall risk in very small. The LAW vault inventory and initial contaminant concentrations are provided in Table F.2.2.6 and F.2.2.19, respectively.

F.4.6.2 Calculated Impacts for the Nominal Case Scenario

The calculated maximum contaminant concentrations from tank sources (i.e., waste released during retrieval from SSTs and residual waste released from SSTs and DSTs) are provided in Table F.4.6.5. Maximum calculated contaminant concentrations from the LAW vault sources are the same as were calculated for the Ex Situ Intermediate Separation Alternative LAW vault sources (Table 3.5.2).

The calculated concentrations from tank sources are lower than calculated concentrations for the Ex Situ Intermediate Separations alternative tank sources (Table F.3.5.1), as would be expected. Absent from this scenario is the impact of Np-237 because with a K_d of 1 mL/g, its movement in the vadose zone is sufficiently retarded such that it does not reach the unconfined aquifer within the 10,000-year period of interest. Provided in Volume Three, Appendix D, are the calculated risk values based on the nominal case groundwater concentrations.

G.1.0 INTRODUCTION

This appendix describes the air dispersion modeling that was performed to assess the impacts on air quality resulting from normal operations associated with the various Tank Waste Remediation System (TWRS) alternatives. The analyses were conducted to accomplish the following objectives:

- Compare the analyzed impacts of potential criteria pollutant releases against National Ambient Air Quality Standards and applicable Washington State regulations;
- Compare the analyzed impacts of emissions of toxic and hazardous air pollutants against applicable Washington State regulations; and
- Compare the analyzed impacts of emissions of radionuclides against applicable Washington State and Federal standards.

The following sections describe the proposed Hanford Site TWRS alternatives and discuss the dispersion models used in the analyses. The remaining sections describe the methodology of the modeling approach, the data used as input to the model (meteorology, source, and receptor parameters), and the results of the modeling effort.

G.2.0 DESCRIPTION OF ALTERNATIVES

The remedial alternatives are broadly separated into those activities related to remediating the tank waste, and those activities involving remediation of the cesium (Cs) and strontium (Sr) capsules. The following alternatives were studied:

- Tanks Waste Alternatives
  - No Action - The waste would be maintained in the existing tanks.
  - Long-Term Management - The double-shell tank (DST) waste would be transferred to newly constructed DSTs. The tanks would be replaced twice, at 50-year intervals.
  - In Situ Fill and Cap - Waste would be disposed of in situ by filling the tanks with gravel and placing a Hanford Barrier over them to inhibit infiltration of rain water or human intrusion.
  - In Situ Vitrification - The waste contained in the existing storage tanks would be vitrified in-place.
  - Ex Situ Intermediate Separations - The tank waste would be separated into high-level waste (HLW) and low-activity waste (LAW) and the waste vitrified. The LAW would be disposed of onsite in subsurface vaults, and the HLW would be shipped offsite for disposal at the potential geologic repository.
  - Ex Situ No Separations - Under the vitrification option, the waste would be immobilized as glass cullet. Under the calcination option, the waste would be treated at temperatures below those required for vitrification, with a resulting dry-powder waste form. All of the treated waste would be shipped offsite for disposal at the potential geologic repository.
  - Ex Situ Extensive Separations - This is an extension of the Ex Situ Intermediate Separations alternative. The difference is that waste would undergo a more extensive series of processing steps that would result in a smaller volume of HLW and a larger volume of LAW. Vitrification and disposal activities would be similar to those in the Ex Situ Intermediate Separations alternative.

- Ex Situ/In Situ Combination 1 and 2 - These alternatives are a combination of the Ex Situ Intermediate Separations alternative and the In Situ Fill and Cap alternative. Waste would be retrieved from 70 tanks (Combination 1) or 25 tanks (Combination 2) , separated into LAW and HLW, and vitrified. The LAW would be disposed of onsite in LAW vaults, and the HLW would be shipped offsite for disposal at the potential geologic repository. The remainder of the tanks (107 under Combination 1 and 152 under Combination 2) would undergo fill and cap, as described for the In Situ Fill and Cap alternative.
- Phased Implementation - For the first phase of this alternative, two demonstration vitrification facilities would be built and operated. One facility would treat LAW, while the other would separate and treat LAW and HLW streams. For the second phase of this alternative, the facilities from the first phase would continue to operate and large-scale facilities would be built to separate the tank waste into HLW and LAW. The LAW would be disposed of onsite in subsurface vaults, and the HLW would be shipped offsite for disposal at the potential geologic repository.

- Cesium and Strontium Capsules Alternatives
  - No Action - The capsules would be maintained in the Waste Encapsulation and Storage Facility (WESF).
  - Onsite Disposal - The capsules would be transferred from their existing location to a newly constructed drywell storage facility.
  - Overpack and Ship - The capsules would be retrieved from their existing location, transferred to a newly constructed repackaging facility, repackaged, and transferred to a storage location pending future disposal at the potential geologic repository.
  - Vitrify with Tank Waste - The capsules would be retrieved, and the contents would be vitrified along with the HLW.

G.2.1 SOURCE IDENTIFICATION AND CHARACTERIZATION

Reviewing available data resulted in identifying several locations and processes expected to emit air pollutants (WHC 1995c, j, n, and Jacobs 1996). The following discussion describes the location and nature of each of these sources. Section G.2.2 details the manner in which these sources were grouped to analyze each alternative. Section G.3.1.2 discusses the emission rates assigned to each source for each alternative.

Pollutant emitting activities were depicted as either area sources or point sources in the dispersion models. Area sources are used for simulating emissions that exist in a known area of activity, especially if the exact source locations are unknown or are expected to move from time to time. In other words, the emissions occurring within the area need not be uniform over space or time. Area sources are defined in the model as square areas and are assigned an areal emission rate (typically specified as grams per square meter per second [$g/m^2/s$]). In this study, the area sources were chosen to include the area in which most of the emissions from a particular operation or grouping of sources would be expected to occur.

Point sources are used for simulating the emissions from sources that are expected to remain in a fixed location and are vented through a stack. The models consider the effects of elevated release heights, building downwash, release temperature, and release velocity when calculating predicted concentrations from point sources. Figure G.2.1.1 shows the source locations used in the modeling scenarios.

Tank Farms

Area sources were used to represent logical groupings of tanks and tank farms. Locations of all sources for all alternatives are shown in Volume Two, Appendix B. Eleven such groupings (identified as TF1E through TF11E) were assigned to tanks in the 200 East Area, while six groupings (TF1W through TF6W) were assigned to the tanks in the 200 West Area. Air emissions that are assumed to occur in these areas include:

- Vehicular emissions associated with construction activities at these sites; and
- Emissions of radiological and nonradiological components from the tanks for all alternatives during continued operations, retrieval, and gravel filling operations.

Waste Retrieval Annex Areas

As part of the ex situ alternatives, the Ex Situ/In Situ Combination 1 and 2 alternatives, and the Phased Implementation alternative, waste transfer annexes would be constructed to collect and distribute the waste retrieved from the tanks. Two such facilities (identified as TA1E and TA2E) are expected to be constructed in the 200 East Area, while three facilities (TA1W, TA2W, and TA3W) would be constructed in the 200 West Area. All annexes would be the same size, except the facility identified as TA2W, which would be larger and also serve as a waste sampling facility.

Although no emissions would be expected to result from operating these facilities, vehicular emissions and fugitive dust would be produced during their construction. These sources were depicted as area sources in the dispersion models.

Concrete Batch Plant

A concrete batch plant would be constructed to support construction activities. For each model scenario, the batch plant was assumed to have sufficient capacity to support the remediation activities. For the purpose of impact assessment, this batch plant was assumed to be located between the 200 Areas. The emissions from this process were modeled as an area source (identified as BTCH).

Figure G.2.1.1 Emission Source Locations

Process Facilities and Tank Farm Construction

Emissions from constructing the processing facilities related to the ex situ and Ex Situ/In Situ Combination 1 and 2 alternatives would include vehicle exhaust emissions and fugitive dust released during earthmoving operations. A single area source (identified as PROC) centered on and equal in size to the disturbed area (80 hectares [ha] [200 acres (ac)]) expected for constructing the process facilities for the Ex Situ Intermediate Separations alternative was used to model these emissions. Bounding case construction emissions related to constructing retrieval equipment at the tank farm locations were modeled as an area source at the tank farm designated TF6W.

For the first phase of the Phased Implementation alternative, two processing facilities would be constructed. Emissions associated with this activity would include vehicle and heavy equipment exhaust emissions and fugitive dust releases. A single area source (FCPI), which encompasses the locations of both plants, was used to model these emissions. In addition, particulate matter emissions from the Pit 30 site (BTCH) would occur.

During the second phase of this alternative, large-scale facilities would be constructed to treat the remainder of the tank waste. Emissions would come from constructing the five waste transfer annexes, process facilities, and a concrete batch plant. Emissions from erecting retrieval equipment at the tank farms would occur simultaneously.

Borrow Site Excavation

For the In Situ Fill and Cap alternative, particulate matter emissions would result from the use of heavy equipment to excavate and transport borrow materials from Pit 30, which is located between the 200 East and 200 West Areas at the same location as the concrete batch plant (BTCH).

For all tank waste alternatives except the No Action alternative, excavation of borrow materials from the Vernita Quarry and McGee Ranch would result in similar particulate matter emissions. These emissions would be associated with installing post-closure barriers over the tank farms. Because of a lack of data concerning these operations, specific emissions estimates and modeling were not performed. However, any such operations would include appropriate control measures (such as using surfactants and water spray procedures) that would result in compliance with Federal and State air quality standards.

Process Facilities Operation

Essentially all the emissions during the processing operations for the ex situ alternatives and the Ex Situ/In Situ

Combination 1 and 2 alternatives would occur through the main processing facility stacks. The LAW and HLW processing facilities stacks for the Ex Situ Intermediate Separations alternative were designated as ST-L and ST-H, respectively. The Ex Situ No Separations alternative would have one stack, identified as SMIN. Although two plants would operate in the Ex Situ Extensive Separations alternative scenario, emissions from both plants would be routed through a common stack, designated as ESEP. Processing facilities for the Ex Situ/In Situ Combination 1 and 2 alternatives would be similar to, but with less capacity than, facilities for the Ex Situ Intermediate Separations alternative. Because stack locations and release parameters are expected to be similar, these stacks were modeled using sources ST-L and ST-H. All stacks were modeled as point sources.

Emissions from the vitrification processing facilities that would be constructed for the Phased Implementation alternative would be routed through stacks. The stack for the Phase 1 LAW processing facility was designated as SSPI, while the Phase 1 combined LAW/HLW processing facility stack was designated as NSPI. The stacks for the Phase 2 full-scale LAW processing facilities were designated as ST-L1 and ST-L2. The full-scale processing facility stack was designated as ST-H. All stacks were modeled as point sources.

In Situ Vitrification Process Stacks

During vitrification operations for the In Situ Vitrification alternative, off-gases would be treated and released through one process stack per tank farm. Although two tanks from a single tank farm would be vitrified simultaneously, it was assumed that emissions from both vitrified tanks would be discharged from a single stack. The facility location that would produce the highest impact (in association with the construction emissions) was identified to be at the tank farm location known as TF6W. A point source (identified as IS6W) was used to model emissions from the process stack.

Drywell Storage Facility

A Drywell storage facility would be constructed as part of the Onsite Disposal alternative for the Cs and Sr capsules. The emissions resulting from the construction of this facility are represented as an area source identified as DWSF. No emissions were assumed to result from the operations phase of this alternative.

Capsule Packaging Facility

The capsules Overpack and Ship alternative would involve emissions resulting from constructing and operating a Capsule Packaging Facility (CPF). These emissions are represented by an area source identified as CPF.

Waste Encapsulation and Storage Facility

Routine radiological emissions from the WESF were analyzed for all alternatives. These emissions would occur through a stack, and were modeled as a point source (WESF).

Evaporator

Operating an evaporator during continued operations and waste processing operations is expected to release radiological and nonradiological components. These emissions would occur through a stack, and were modeled as a point source (EVAP).

W-314 Project

This project potentially involves the replacement of various transfer lines located in the 200 East and 200 West Areas. The data available for this project indicate that construction activities would be spread out over various areas and would be of relatively low intensity compared to construction activities associated with other TWRS alternatives. In addition, dust-control measures would be employed that would minimize emissions from these activities. Because substantial emissions are not anticipated, the emissions from the W-314 Project were not separately analyzed.

G.2.2 MODEL SCENARIOS

The various alternatives would involve emissions from one or several of the sources described previously. Implementing alternatives would involve an initial phase of facility construction followed by a phase during which the treatment, transfer, or repackaging processes would occur. Consequently, each alternative could have different phases in which the emissions and analyzed impacts were distinctly different. Therefore, the emissions and analyzed impacts resulting from each phase were calculated and are reported separately for each alternative. The following sections discuss each proposed TWRS alternative and describe the associated emissions sources.

G.2.2.1 Tank Waste Alternatives

No Action Alternative (Tank Waste)

The No Action alternative would involve routine radiological and nonradiological emissions from continued operation of the storage tanks, and continued operation of the evaporator as a waste management activity. In addition, routine radiological releases from WESF would occur and are considered. No construction activities would be associated with this alternative.

The emissions from the continued operations of tank farms would also occur during the construction and operation phases of the alternatives, and are included in the analysis of these alternatives.

Long-Term Management Alternative

The Long-Term Management alternative would involve two phases having air emissions, each of which was analyzed separately. The first phase would involve transferring waste from existing DSTs to newly constructed DSTs 50 years in the future. Waste from the SSTs would not be retanked. The new tanks would be constructed in the same area as the process facility that would be built for the Ex Situ Intermediate Separations, Ex Situ No Separations, and Ex Situ Extensive Separations alternatives; the construction emissions were modeled by assigning them to the location PROC. In addition, continued tank and evaporator emissions would occur simultaneously at the tank farms and the evaporator locations. Increased emissions would be expected from tanks undergoing retrieval. These increased emissions were modeled by assigning the highest increased emission rate for each pollutant to the TF6W Tank Farm, which was identified as the tank farm location producing the highest impacts. The actual emissions for every chemical would not necessarily be the highest at TF6W.

The emissions from the tank farms during retrieval operations would be the same as would be expected for retrieval activities associated with the operational phases of the Ex Situ (Intermediate Separations, No Separations, and Extensive Separations) alternatives. These impacts have been included with the analysis of these alternatives.

The second phase (replacement of the tanks 100 years in the future) is similar to the first phase, except that the routine and increased tank emissions would occur within the PROC area, as well as the construction emissions.

In Situ Fill and Cap Alternative

Implementing this alternative would involve construction and gravel-filling operations at the tank farm locations, as well as gravel removal from Pit 30.

For the purposes of the analysis, construction activities are assumed to occur simultaneously with the filling operations and routine emissions from the continued operation of the tank farms. The following text summarizes the pollutant emitting activities and sources for this alternative.

- Particulate matter emissions are expected as a result of gravel handling operations at Pit 30 (BTCH).
- Construction equipment emissions are expected at the tank farm location. To provide a conservative approach, emissions from construction activities were assigned to the bounding case location (TF6W).
- Gravel handling operations are assumed to occur at a location central to several tank farms; the corresponding emissions were assigned to location TF5W.
- Increased tank emissions during filling operations are expected. To ensure a conservative approach, the increased

tank emissions were assigned to location TF6W in a similar manner as was done for retrieval operations.

The emissions from the tank farms during gravel filling operations would be the same as would be expected during the in situ portion of the Ex Situ/In Situ Combination 1 and 2 alternatives and have been included in the analysis of that alternative.

In Situ Vitrification Alternative

Implementing this alternative would involve constructing a tank farm confinement facility and an off-gas treatment facility at each tank farm. Construction of one confinement facility would occur while vitrification processes were occurring at an adjacent tank farm. For potential air quality impacts, the bounding case location for construction was identified as TF6W, and the impacts described are for this bounding case scenario.

Operations associated with this alternative would release pollutants that would be treated in an off-gas treatment facility. The emissions from the off-gas treatment facility would be from a vertical stack. The bounding case location for this operation was shown to be adjacent to TF6W. Although construction and operations activities would not occur at the same time and at the same tank farm location, the operational emissions were assigned to this location (IS6W) to provide a bounding case analysis.

Ex Situ Intermediate Separations Alternative

The construction phase would involve vehicular and fugitive dust emissions from constructing five waste transfer annexes and two waste processing facilities and constructing and operating a concrete batch plant to support these operations. Additionally, vehicular emissions associated with constructing tank waste retrieval equipment at the tank farms would occur during this time.

According to the estimated construction schedule, work would not be expected to occur at more than two tank farms at a time. An analysis was conducted to determine the two locations that would produce the highest impact when construction activities occurred simultaneously. It identified the TF5W and TF6W areas as having the highest combined impacts. Accordingly, the impacts of these activities were analyzed by assuming simultaneous construction operations at:

- The process facility locations;
- The concrete batch plant;
- The five transfer annex areas (TA1W, TA2W, TA3W, TA1E, TA2E); and
- Two tank farm locations (TF5W and TF6W).

The operational phase of the Ex Situ Intermediate Separations alternative would involve separating the waste into HLW and LAW streams and processing the waste at separate facilities. HLW vitrification processing would occur over a 12-year period while LAW processing would occur over a 19-year period. Additionally, retrieval equipment would operate at no more than two tank farm locations at a time during the course of the processing. Therefore, the impacts of the operations phase of the alternative were calculated by evaluating the simultaneous operation of both processing facilities (ST-L and ST-H) and the two tank farm locations (i.e., TF5W and TF6W) producing the highest impacts.

Ex Situ No Separations Alternative

The emission scenario for the Ex Situ No Separations alternative differs from the Ex Situ Intermediate Separations alternative because the tank waste would not be separated into LAW and HLW components and only one processing plant with one process stack (as opposed to two) would be operated. Two options (vitrification and calcination) were analyzed for this alternative. The sources and emission rates associated with the calcination option are identical to those of the vitrification alternative, with the exception of the emission rates of nitrogen oxides and carbon-14 (C-14) (Jacobs 1996).

The construction phase would involve vehicular and fugitive dust emissions from constructing the five waste transfer annexes and the process facilities, and from constructing and operating a concrete batch plant to support these operations. Additionally, vehicular emissions from erecting the retrieval equipment at the tank farms would occur during this time. These emissions were assigned in the same manner as described for the Ex Situ Intermediate Separations alternative construction phase, although emission rates would differ.

Operational processes for the Ex Situ No Separations alternative would occur over a 14-year period, beginning after completion of the construction phase. Emissions would occur through the main process stack at the vitrification facility. Additionally, installing and operating retrieval equipment would occur at only two tank farm locations at a time during processing. Therefore, the impacts of the operations phase of the alternative were calculated by evaluating the simultaneous operation of the process facility and the two tank farm locations (i.e., TF5W and TF6W) producing the highest combined impacts.

Ex Situ Extensive Separations Alternative

The construction phase would involve vehicular and fugitive dust emissions from constructing the five waste transfer annexes and the process facilities, and from constructing and operating a concrete batch plant to support these operations. Additionally, vehicular emissions from erecting the retrieval equipment at the tank farms would occur during this time. These emissions were assigned in the same manner as described for the Ex Situ Intermediate Separations alternative construction phase, although emission rates would differ.

The operational phase of this alternative would involve separating the tank waste into HLW and LAW streams and processing the waste at separate facilities. HLW and LAW processing vitrification processing would occur over a 21-year period. The off-gas emissions from these two processes would be combined and routed through a common stack (ESEP). In addition, retrieval equipment would be operated at only two tank farm locations at a time during processing. Therefore, the impacts of the operations phase of the alternative were calculated by evaluating the simultaneous operation of the process facilities (ESEP) and the two tank farm locations (i.e., TF5W and TF6W) producing the highest combined impacts.

Ex Situ/In Situ Combination 1 and 2 Alternative s

Implementing the in situ portion of these alternative s would involve the same source locations and emissions scenarios as described for the In Situ Fill and Cap alternative, although lower emission rates would be expected. These emissions would occur simultaneously with those associated with the operational phase of the ex situ portion of the alternative s .

The construction phase s would involve vehicular and fugitive dust emissions from constructing the waste transfer annexes and the process facilities, and from constructing and operating a concrete batch plant to support these operations. Additionally, vehicular emissions from erecting the retrieval equipment at the tank farms would occur during this time. These emissions were assigned in the same manner as described for the Ex Situ Intermediate Separations alternative construction phase, although emission rates would differ.

The operational phase of the ex situ vitrification portion of the alternative s would involve separating the HLW and LAW streams and processing the waste at separate facilities. Retrieval and ex situ vitrification operations would be expected to occur over a 21-year period for Combination 1, and over a 20-year period for Combination 2. Additionally, retrieval equipment would be expected to operate at no more than two tank farm locations at a time during processing. Therefore, the impacts of the operational phase of these alternative s were calculated by evaluating the simultaneous operation of both process facilities (ST-L and ST-H) and the two tank farm locations (i.e., TF5W and TF6W) producing the highest impacts.

Phased Implementation Alternative

Phase 1

Implementation of the first phase of this alternative would involve a construction period, during which two vitrification facilities would be constructed. Because construction on both facilities would occur simultaneously, the construction emissions were assigned to a single area source (FCPI) that would encompass the expected disturbed area.

Following completion of construction, operation of the two facilities would commence. Emissions from the vitrification processes would be released through two stacks -- one located at the combined LAW/HLW facility (NSPI), and one located at the LAW facility (SSPI). LAW operations at both plants would occur over a 10-year period; HLW operations at the combined plant would occur for 6 years. The impacts from these activities were calculated by using the peak hourly emission rates from all processes simultaneously.

Phase 2

In the second phase of this alternative, large-scale facilities would be constructed to treat the remainder of the tank waste. Emissions would come from constructing the five waste transfer annexes (TA1W, TA2W, TA3W, TA1E, TA2E), process facilities, and a concrete batch plant (BTCH). Emissions from erecting retrieval equipment at the tank farms producing the highest impacts (TF5W, TF6W) would occur simultaneously. These emissions were assessed in the same manner as described for the Ex Situ Intermediate Separations alternative.

Total Alternative

Impacts from the operation of the total Phased Implementation alternative are analyzed in the same manner as for the Ex Situ Intermediate Separations alternative. This involves the simultaneous operation of the two facilities discussed under Phase 1 (NSPI and SSPI), the large-scale facilities (ST-L 1, ST-L2 and ST-H), and the two tank farm locations producing the highest impacts (TF5W and TF6W).

G.2.2.2 Cesium and Strontium Capsule Alternatives

No Action Alternative (Capsules)

This alternative would involve maintaining the capsules at WESF. Routine radiological emissions from WESF were analyzed for this alternative and were included in the analysis of all other alternatives. These emissions were modeled as a point source (WESF). No other impacts are expected from this alternative.

Onsite Disposal Alternative

This alternative would involve transferring the existing capsules to a newly constructed Drywell storage facility. Constructing the Drywell storage facility would result in emissions from construction. These construction emissions were assigned to the source identified as DWSF. There would be no emissions during operations for this alternative. No airborne emissions are anticipated from the sealed Cs and Sr capsules while they are in storage. The only operational activities would be facility monitoring.

Overpack and Ship Alternative

This alternative would involve recovering the capsules from WESF, repackaging them, and shipping them to the potential geologic repository. A repackaging facility would be built as part of this alternative. Construction emissions and minor operational emissions would occur. These emissions were assigned to the area source identified as CPF.

Vitrify with Tank Waste Alternative

This alternative would involve recovering the Cs and Sr capsules from WESF, removing the contents, and vitrifying the capsule contents along with tank waste. Because the emissions occurring under this alternative are combined with emissions from remediating tank waste, no separate air quality impacts were analyzed.

G.3.0 MODEL SELECTION AND METHODOLOGY

Version two of the U.S. Environmental Protection Agency (EPA) Industrial Source Complex Model (ISC2) was selected to perform the air-dispersion modeling (EPA 1992a). The ISC2 model is a Gaussian dispersion model capable of simulating emissions from diverse source types. In a Gaussian dispersion model, pollutant concentrations are assumed to be distributed normally (i.e., bell-shaped curve) about the centerline of the plume, a relationship that has been observed to occur for releases of gases and small particles from many types of sources. ISC2 is a guideline air quality model (i.e., it is accepted by EPA for regulatory applications [40 CFR Part 51]). It is also routinely recommended for performing screening and refined analyses for remedial actions at Resource Conservation and Recovery Act and Superfund sites (EPA 1989a). This model was selected based on its widespread acceptability and versatility.

The ISC2 consists of two models: a short-term version (ISCST2) appropriate for predicting concentrations averages of 1 to 24 hours, and a long-term version (ISCLT2) for predicting seasonal and yearly concentrations. Both models were incorporated in this study. ISCLT2 was used to generate annual average predicted concentrations for comparison with annual average ambient air quality standards and target levels. ISCST2 was executed in a screening mode to predict short-term ambient air concentrations for comparisons to 1 to 24 hour average air quality standards and other target levels (EPA 1992b).

G.3.1 MODEL OPTIONS AND INPUTS

ISC2 requires the input of source and meteorological data as well as receptor coordinates (i.e., locations for which the model computes a concentration). The model must also be configured properly by the selection of various options. The following discussions document the inputs and model configuration.

G.3.1.1 Model Options

The models were run using the standard rural dispersion coefficients. These were selected based on the nature of the land use in the vicinity of the emission sources. Standard EPA procedures were followed in making this determination (40 CFR Part 51).

The regulatory default option was selected, which implemented the following model options:

- Final plume rise;
- Buoyancy-induced dispersion;
- Default wind profile exponents;
- Default vertical potential temperature gradients; and
- Upper bound values for supersquat buildings.

G.3.1.2 Source Data

The manner in which sources were grouped for each alternative is discussed in Section G.2.2. Source- related model input data are shown on Table G.3.1.1. Please note that all tables are located at the end of Appendix G. The chemical pollutant emission rates for each phase of the alternatives are shown in Tables G.3.1.2 through G.3.1.1 9 . Tables G.3.1. 20 through G.3.1. 31 contain the radiological emission rates. When appropriate, construction and operational emissions from the alternatives were analyzed separately, and separate emissions data for construction and operational activities are reported. In other cases, construction and operational processes would occur simultaneously, and the emission rates reported represent the combined emissions from construction and operational activities.

The primary sources of data used for the emission rates were the engineering data packages for the various alternatives, which were prepared by the Hanford Site Management and Operations contractor (WHC 1995 a, b, c, d, e, f, g, h, i, n) and the TWRS EIS contractor (Jacobs 1996). The following discussion describes the protocol used for calculating model emission rates from the available data.

Routine Emissions from Tank Farms and the Waste Encapsulation and Storage Facility

Routine emissions of radiological and nonradiological components from continued operations of the tank farms and

WESF are shown for the No Action alternative (Tank Waste) in Tables G.3.1.2 and G.3.1. 20 . Emissions are reported separately for each tank farm location (Jacobs 1996). Similar emissions are expected to occur and were analyzed for all alternatives. However, during retrieval operations (and during gravel filling operations associated with the In Situ Fill and Cap alternative), the routine emissions rates would be expected to increase at the affected tank farm location. In these situations, the increased emission rates were analyzed in the following manner: the highest routine emission rate for each pollutant was assigned to source TF6W to provide a bounding case scenario and increased by the appropriate factor to represent retrieval or gravel filling operations.

In Situ Vitrification Emission Data

Data contained in the engineering data packages for this alternative were analyzed to generate tables of radiological and nonradiological emissions for this alternative (Jacobs 1996). Separate emissions data for the construction and operational phases for the alternative were created. Annual construction emissions were converted to peak hourly emissions based on an assumed schedule of construction activities. The peak hourly emission rate of each pollutant for the vitrification process was used for the model input.

Process Facility Stack Emissions Data

Process flow diagrams and mass balance data contained in the engineering data packages were analyzed to generate tables of average annual emissions, maximum daily emissions, and peak hourly emissions from the vitrification facility process stacks for the Ex Situ Intermediate Separations, Ex Situ No Separations, and Ex Situ Extensive Separations alternatives, including the Ex Situ/In Situ Combination 1 and 2 and the Phased Implementation alternatives (Jacobs 1996). The peak hourly emissions for pollutants listed in these tables were used to generate emission rates for the process stacks.

Construction Activities Emission Data

The primary sources of construction activity emission data were the engineering data packages for the various alternatives. In some cases, data concerning the construction emissions were not given explicitly in the data package. Calculations were performed to estimate the emissions given the scope of the construction activity (Jacobs 1996). Annual emissions were converted to hourly emissions based on an assumed schedule for construction activities.

G.3.1.3 Meteorological Data

Long-Term Meteorological Data

The meteorological data used for the ISCLT2 model consisted of a joint frequency distribution, also referred to as a stability array (STAR) of wind speed, wind direction, and stability class compiled for each of 5 years (1989 to 1993). The stability arrays are shown in Tables G.3.1.33 through G.3.1.37. These data were based on measurements collected at the Hanford Meteorological Station located between the 200 East Area and 200 West Area (PNL 1994g). The general wind direction is to the southeast.

Additional meteorological data, such as the annual mean temperature and mixing heights, were obtained from the Hanford Climatological Data Summary (PNL 1994g) and a standard summary document of morning and afternoon mixing heights (Holzworth 1972). The protocol for assigning these values was taken from the ISC2 User's Manual (EPA 1992a). As outlined in the user's manual, the average annual maximum daily temperature (18 C [65 F]) was used for the A, B, and C stability classes; the average minimum daily temperature (5 C [42 F]) was used for the stability classes E and F; and the average annual temperature (12 C [53 F]) was used for the D stability class. Mixing height values were assigned as follows: 1.5 times the average afternoon mixing height of 1,500 m (4,900 ft) was used for stability class A and the average afternoon mixing height was used for stability classes B, C, and D. Because ISCLT2 in the rural mode assumes that there is no restriction in vertical mixing in the E and F stability classes, 1.5 times the average afternoon mixing height was considered to be appropriate for these stability classes.

Short-Term Meteorological Data

ISCST2 requires hourly meteorological data. Typically, for refined and regulatory modeling, a full year of sequential hourly records are input to the model. Because data in this format for the Hanford Site were unavailable and a refined level of modeling was not considered necessary given the preliminary nature of the design data, the ISCST2 model was executed in a screening mode. This required inputting a range of possible meteorological conditions which might reasonably occur at this site. This screening meteorological file was prepared according to procedures outlined in EPA's SCREEN2 Model User's Guide (EPA 1992c).

For each of 36 wind directions, 54 possible combinations of stability class and wind speed were input (i.e., 1,944 hourly records). A matrix of windspeed and stability classes is shown in Table G.3.1. 32 .

Atmospheric mixing heights were assigned to stability classes A, B, C, and D using the mechanical mixing height (Z_m) and calculated using the following formula taken from Section 3.2 of the SCREEN2 Model User's Guide:

Where:

Z_m = mechanical mixing height (m)
u_{10} = wind speed at 10 m elevation (m/s)

To allow for unlimited mixing, heights of 10,000 m (32,800 ft) were assigned to stability classes E and F, in keeping with the scheme outlined in the SCREEN2 User's Manual. Ambient temperatures for each stability class were assigned in the same manner as the ISCLT2 model inputs.

G.3.1.4 Receptor Locations

Three receptor sets were used for the study. The first set was used to predict concentrations for comparison with Washington State and Federal ambient air quality standards and target levels for nonradionuclide impacts, and for comparison with the Washington State ambient air quality standard for radionuclides. These receptor locations were placed to correspond to areas that might be considered to be ambient air (i.e., areas where the general public could be exposed). Because of the potential release of the Fitzner Eberhardt Arid Lands Ecology portion of the Hanford Site, the public would have access to land southwest of State Route 240, and it was selected to represent the southern boundary of the facility. For the same reason, the Columbia River was selected to define the northern and eastern facility boundaries. A total of 614 receptors were placed along the Columbia River, State Route 240, and the Hanford Site boundary line north of the Columbia River. Because of the size of the Hanford Site, most offsite receptors are quite distant from the sources and were placed with a 2-km (1.2-mi) spacing. To ensure that the areas of maximum impact were identified, receptors were placed at 500-m (1,650-ft) intervals along sections of State Route 240 to ensure adequate coverage.

The second set of receptors was used to assess compliance with the Federal standard for radionuclide release impacts contained in 40 Code of Regulations [CFR] Part 61. Compliance with this standard is calculated at the nearest residence, rather than at the nearest ambient air location. Although the distance from the source locations to the nearest residence in all directions is not known, available data indicate that no residence lies within 24 km (15 mi) of the 200 West area, or 16 km (10 mi) of the 200 East Area (DOE 1994d). Thus, a circular set of 72 receptors, centered on the 200 West Area and with a radius of 24 km (15 mi), was established to assess compliance with this standard. This circular grid encompasses all locations within 16 km (10 mi) of the 200 East Area.

A rectangular grid of 834 receptors, which encompasses the entire Hanford Site, was used to generate isopleths of radionuclide impacts.

ISC2 is designed to model simple terrain (i.e., terrain less than or equal to stack height). Terrain elevation is relevant for modeling point sources. Concentration predictions from area source emissions are not affected by terrain. Elevations for all receptor locations were obtained from a Geographic Information System database of the Hanford

Site and U.S. Geological Survey topographical maps of the surrounding area.

G.3.2 MODEL OUTPUT

The model output consisted of ground level average concentration values. ISCLT2 produced annual average concentrations for each of the 5 years (1989 to 1993) of meteorological input data. The predicted concentrations reported are from the year producing the highest impact. ISCST2 was executed to determine the maximum 1-hour average concentrations resulting from inputting a range of possible meteorological conditions. The 1-hour averages were multiplied by various correction factors for predictions of 3-, 8-, and 24-hour average concentrations. The following sections provide more details on the concentration calculations.

G.3.2.1 Normalized Concentrations

To provide efficiency in processing the results and flexibility for incorporating future changes, the sources were modeled with unit emission rates, resulting in predictions of normalized concentrations (also referred to as Chi/Q values).

The normalized concentrations, having dimensions of 1.0E-06 seconds/cubic meter (s/m^3), were produced by assigning each source a unit emission rate of 1.0 grams per second (g/s). The concentration at a receptor was calculated by multiplying the actual emission rate (referred to as the source term) by the appropriate Chi/Q value. For example, a source term expressed in units of g/s will produce a concentration given as micrograms per cubic meter ($\mu g/m^3$), and a source term expressed in units of curies per second (Ci/s) will produce a concentration given as $\mu Ci/m^3$.

The total concentration at any receptor consists of the sum of the concentrations contributed by each emitting source. Therefore, the total concentration at a receptor with *n* contributing sources is calculated as follows:

Where:

C_{total} = total concentration ($\mu g/m^3$ or $\mu Ci/m^3$)
$(Chi/Q)_n$ = predicted Chi/Q value (1.0E-06 s/m^3) for source *n*
T = source term (g/s or Ci/s) for source *n*

Separate Chi/Q plot files were generated for each of the 30 identified sources. To calculate the total concentration values these plot files have been entered into spreadsheets. These spreadsheets allow the input of source terms of interest for each pollutant and the calculation of total concentration values at each receptor location.

G.3.2.2 Averaging Time Conversions

Values for 3-, 8-, and 24-hour averages were obtained by multiplying the calculated 1-hour average concentration by the following conversion factor: 0.9 for 3-hour averages, 0.7 for 8-hour averages, and 0.4 for 24-hour averages (EPA 1992b).

G.4.0 MODEL RESULTS

The results of the modeling were compared with Washington State air quality standard or acceptable source impact levels. Washington State standards are listed in the Washington Administrative Code (WAC) and include:

- Acceptable Source Impact Levels for toxic air pollutants (WAC 173-460);
- Ambient Air Quality Standards for particulate matter (WAC 173-470);

- The Ambient Air Quality Standards for sulfur oxides (WAC 173-474);
- The Ambient Air Quality Standards for carbon monoxide ozone and nitrogen dioxide (WAC 173-474);
- The Ambient Air Quality Standards for radionuclides (WAC 173-480); and
- The Ambient Air Quality Standards for fluorides (WAC 173-481).

The results were also compared with national primary and secondary Ambient Air Quality Standards listed in 40 CFR Part 50. The Washington Ambient Air Quality Standards are equal to or are more stringent than the National Ambient Air Quality Standards, and thus compliance with the Washington Ambient Air Quality Standards implies compliance with the National Ambient Air Quality Standards.

Predicted maximum emissions for hazardous air pollutants and pollutants for which a Washington Acceptable Source Impact Level exists are provided along with the applicable level. Modeling results for chemical pollutants are given in Tables G.4.0.1 through G.4.0. 20 . Modeled impacts for key radionuclides during operations are plotted in Figures G.4.0.1 through G.4.0. 13 and presented for each alternative in Tables G.4.0. 21 through G.4.0. 32 . The modeling results show radionuclide emissions converted to doses and compares them to Washington Air Quality Standards for radiation doses contained in WAC 173-480 and Federal standards for radioactive emissions from DOE facilities (40 CFR 61, Subpart H). The Ambient Air Quality Standard (WAC 173-480) for the maximum accumulated dose equivalent at any offsite receptor from a commercial nuclear facility is 25 mrem/yr. As a Federal facility, the Hanford Site could be expected to comply with the EPA regulation (40 CFR 61), which limits the maximum predicted dose at the nearest residence to 10 mrem/yr dose equivalent. Uranium-235 (U-235) was not included in the impacts for radionuclides. Uranium trioxide was, however, analyzed as a hazardous air pollutant. This approach is consistent with the risk analysis for routine operations for each alternative, because the chemical toxicity of uranium is much greater than its radiological hazard. Additionally, emissions of U-235 were determined to have a very small contribution to overall risk.

The modeling results for all alternatives show no exceedances of Federal or State air quality standards for criteria pollutants, hazardous air pollutants, or radionuclides. Substantial impacts from all sources (those that exceed 10 percent of the applicable standard) are listed in the following text:

Particulates	The impacts, as a percentage of the Federal and State 24-hour standard, that would occur during the construction phases of the In Situ Vitrification alternative (64 percent of the standard) and the construction phases of the Ex Situ Extensive Separations, Ex Situ Intermediate Separations, and Ex Situ No Separations) alternatives (63 percent, 62 percent, and 57 percent, respectively). In addition, substantial impacts occur during the construction phases of the Ex Situ/In Situ Combination 1 and 2 alternatives (34 percent of the 24-hour State and Federal standards), the Phased Implementation Phase 1 alternative (58 percent of the State and Federal 24-hour standard), Phased Implementation Phase 2 (65 percent of the State and Federal 24-hour standard) and the Capsules Onsite Disposal alternative (12 percent of the State and Federal 24-hour standard).
Carbon Monoxide	The impacts, as a percentage of the Federal and State 8-hour standard, that would occur during the construction phases of the Ex Situ Extensive Separations, Ex Situ Intermediate Separations, and Ex Situ No Separations alternatives are 25 percent, 21 percent, and 17 percent, respectively.
Sulfur Oxides	The impacts, as a percentage of the State 1-hour standard, that would occur during the In Situ Vitrification alternative are 10 percent of the standard.
Radionuclides	The impacts, as a percentage of the State annual standard, that would occur during the In Situ Vitrification alternative are 75 percent of standard, with primary contributors being C-14 and iodine-129 (I-129). The impacts, as a percentage of the Federal annual standard, that would occur during the In Situ Vitrification alternative are 24 percent of standard, with primary contributors being C-14 and I-129.

G.5.0 ACCURACY AND UNCERTAINTY

Various assumptions and other factors can introduce uncertainty in air dispersion modeling studies. With regard to the modeling performed to analyze air impacts from the various alternatives, these uncertainties can be broadly separated into the following categories:

- Uncertainty inherent in the air dispersion models;
- Uncertainty in data used as model inputs; and
- Uncertainty in interpretation of model output.

These categories are discussed in more detail in the following text.

G.5.1 AIR DISPERSION MODELING

Air dispersion models are mathematical tools designed to estimate pollutant concentration and/or deposition at specific locations. These predictions are based on various input parameters and physical assumptions, such as the following:

- Pollutant release characteristics (emission rate, temperature, flow rate);
- Meteorological conditions (ambient temperature, mixing height, stability, wind speed and direction, atmospheric temperature and wind speed profile); and
- Pollutant transport behavior (dispersion, plume rise, interaction with terrain).

In an ideal case, the values entered into the model for these known parameters will closely duplicate the range of actual conditions that exist for a particular scenario. However, the stocastic nature of the atmosphere results in other unknown factors (e.g., wind perturbations) that influence the actual dispersion at a particular time or place. It has been estimated that even when the known conditions are exactly duplicated in the model, the unknown factors can contribute to variations in concentration as much as ±50 percent (EPA 1995).

Gaussian air dispersion models are accurate within a factor of two when properly executed with accurate data. In general, models are more reliable when estimating long-term average concentrations as opposed to short-term averages, and are reasonably reliable in estimating the magnitude of the highest concentration occurring, but are not capable of predicting the exact time or position of the occurrence. In other words, the highest concentration that can be expected in an area can be predicted with reasonable accuracy; the location and time that the maximum concentration will occur are less reliably predicted.

The air dispersion models used in this study are considered to be state-of the-art for regulatory modeling and are recommended by EPA for this type of analysis. To compensate for the uncertainties in model results, conservative input values were used that provide conservative (higher than might actually occur under average conditions) results.

G.5.2 MODEL INPUT DATA

Two types of input data are used for the air dispersion models: meteorological data and source data. Both types of input data are discussed in the following text.

G.5.2.1 Meteorological Data

Two types of meteorological data (i.e., long-term and short-term) were used in the dispersion modeling study. Long-term (i.e., annual) average concentrations were estimated using meteorological data collected at the Hanford Meteorological Station from 1989 to 1993. The assumption inherent in this choice is that this data represent future meteorological conditions. A 5-year record is generally accepted as an adequate sample set for modeling purposes. Although long-term climatic shifts may occur, many of the air pollutant emitting activities analyzed in this study are expected to occur within several decades of project initiation, which is a relatively short time frame on a climatic scale. Therefore, the use of this data is not expected to adversely affect the results.

Typically, short-term average (i.e., 1- 3- 8- and 24-hour) concentrations are predicted using hourly meteorological measurements from a station located at, or near, the site of interest. Because the data were not available for this study, a screening approach was taken, and a standard set of hourly meteorological conditions were incorporated in the modeling. These standard conditions are accepted by the EPA to encompass the range of atmospheric stabilities and wind speeds that could be expected to occur anywhere. Each combination of wind speed and atmospheric stability was assumed to occur in every possible wind direction. The predicted concentrations represent the highest value that could be reasonably expected to occur anywhere. This approach is conservative because the meteorological condition leading to the reported result may not occur at the site for all wind directions.

G.5.2.2 Source Data

Data describing the location, emission rate, and emission characteristics of the sources was input to the models. Information concerning pollutant emission rates was derived from data packages supplied by the Site Management and Operations contractor and analyzed by the Environmental Impact Statement contractor. In general, when emissions estimates were being developed, conservative values were used.

The location of the pollutant emitting sources is not known with complete certainty in all cases. Pollutant emitting activities associated with the existing tank farms will occur in the present locations. However, the exact location of future facilities is subject to some uncertainty. In general, the closer a source is to a receptor, the higher the predicted concentration at that receptor will be. As a consequence, if the eventual location of an emitting activity is closer to a plant boundary than depicted in the model, the impacts may be higher. Of course, if the activity is located farther from the boundary than depicted in the model, the impacts may be lower.

The temporal arrangement of the pollutant emitting activities affects the predicted concentrations as well. The predicted concentration at any receptor represents the contributions of each individual emitting source. To properly analyze a scenario, all the pollutant emitting activities that could occur at the same time must be considered. In general, most of the scenarios analyzed involved a period of facility construction followed by an operational period.

In some cases, the location of an emitting source is expected to move from place to place as the project progresses. An example of this would be emissions related to remedial activities at tank farm locations. In most cases, work would be occurring at one or two of the possible 17 locations at one time. Given these uncertainties, a conservative analysis was produced by assuming that activities that might or might not overlap in time would occur simultaneously. In addition, activities that would be expected to move from place to place were modeled as if occurring in the location producing the highest potential impact.

Sources were modeled as either point or area sources. Point sources are used to approximate pollutant releases from a stack or other fixed, functional opening or vent. The dispersion algorithms used for point sources modify the effective release height to take into account plume buoyancy (from a heated release) and momentum (from vertical release velocity). Typically, area sources are used to approximate pollutant releases that do not occur at a single well-defined point, but instead can be defined as occurring within a defined area. For instance, an area source could include many small fixed point sources that were too numerous to model individually, or could made up of several mobile sources that may move about within the fixed area. In this study, the construction activities were represented as area sources. The classification of the sources into these two categories involved some degree of uncertainty and some assumptions as well. The models use different algorithms to represent dispersion from point and area sources and the predicted concentration at a receptor could vary, depending on the algorithm chosen. In general, these effects are more noticeable at locations close to the source and tend to diminish as the distance between source and receptor increases.

G.5.3 INTERPRETATION OF MODEL OUTPUT

The short-term model was run using screening meteorology to produce maximum predicted 1-hour average concentrations. These 1-hour average values were converted to 3- ,8-, and 24-hour average concentrations, when appropriate, to compare to applicable standards. This was accomplished by applying conversion factors to the 1-hour average values. Consistent with modeling guidelines (EPA 1988), the factors of 0.9, 0.7, and 0.4 were applied to convert to 3-, 8-, and 24-hour averages, respectively. These factors involve an implied assumption regarding the persistence of the meteorological condition producing the highest 1-hour impact. In other words, conservative meteorological conditions that produced the highest 1-hour concentration can be expected to persist for most of a 3-

hour period and to a lesser degree over an 8- or 24-hour period. The modeling guidelines indicate a range of values for each conversion factor: the 3-hour conversion factor can range from 0.8 to 1.0, the 8-hour factor from 0.5 to 0.9, and the 24-hour factor from 0.2 to 0.6. Use of the midpoint values was considered appropriate for this study.

H.1.0 INTRODUCTION

This appendix

describes the socioeconomic impact modeling for the Tank Waste Remediation System (TWRS) Environmental

Impact Statement (EIS) alternatives. It describes the methodology and assumptions used in the modeling effort and provides additional

technical information about the analysis. This appendix discusses:

- # The development of the baseline

Hanford Site employment estimates used to assess the socioeconomic impacts of the EIS alternatives;

- # The econometric

forecasting model used to project economic variables; and

- **Details of the employment projections for the EIS alternatives.**

The appendix also includes tables showing socioeconomic impacts for each alternative during each year of the remediation

period, analyzed up to the year 2040.

The socioeconomic impact analysis addresses the Tri-Cities

Metropolitan Statistical Area (MSA), which encompasses all of Benton and Franklin counties. The analysis does not address

impacts on other areas of the region because there are too few Hanford Site employees in the surrounding counties for changes in

Hanford Site employment to cause substantial economic impacts there. Historically, only about 7 percent of the total Site work force has

lived outside Benton and Franklin counties (Cushing 1995). Most of these employees live in Yakima County, which has a total

nonfarm employment of over 65,000 (WSDES 1993b). With Hanford Site employees representing approximately 1

percent of total Yakima County nonfarm employment, the EIS alternatives would have too small an employment

impact to warrant detailed analysis. The analysis does not address potential economic impacts of accidents that potentially could

occur during implementation of the alternatives. Because there is a very low probability that an accident would have major

economic impact, this issue does not warrant detailed analysis. However, Appendix E does provide a discussion of potential impacts

associated with remediation accidents and mitigation measures that would be taken to address those impacts.

It was assumed that the schedule for implementing each alternative would meet the applicable Hanford Federal Facility Agreement

and Consent Order (Tri-Party Agreement) milestones (Ecology et al. 1994). There are uncertainties related to waste

characterization (Appendix A, Section A.3.0) and waste loading (Appendix B, Section B.3.10 and B.8.0) that could affect the

schedules for completing all of the ex situ alternatives. Under conservative case conditions, because of these

uncertainties completing the ex situ alternative could require from one to four years beyond the applicable Tri-Party Agreement

milestones for low-activity waste. However, there are factors that could compensate for these uncertainties and allow the Tri-Party Agreement

schedule to be maintained. For example, it may be possible to achieve a higher percentage of waste loading than projected under

the conservative case. Also, larger processing facilities could be constructed or construction schedules could be accelerated, both

of which could shorten alternatives' schedules for completion.

Section H.1.1 provides a

discussion of the assumptions, data, methodology, and uncertainties directly associated with the development of the baseline scenario

used to calculate and compare the impacts of the EIS alternatives. The major uncertainties are associated with the projection of

future levels of non-TWRS Hanford Site employment and future overall employment in the Tri-Cities MSA. In both cases,

substantial changes in future overall employment would change each alternative's impact on future Hanford Site

employment, Tri-Cities MSA nonfarm employment, population, taxable retail sales, and average home prices. In turn,

changes to the population projection would result in comparable changes to each alternative's impact on public

services and facilities such as schools, police, and fire (Volume One, Section 5.6). Also, changes to the projection of future Hanford

Site employment would result in changes to the analysis of transportation impacts (Volume One, Section 5.10). In each case,

however, the changes in future employment would impact all of the alternatives equally. Therefore, while the level of each impact would

change, the comparison of the relative impacts among the alternatives would not be affected.

In the time

between publication of the Draft EIS and preparation of the Final EIS, revisions have occurred in the schedules of a

number of EIS alternatives. In all cases except for Phase 2 of the Phased Implementation alternative, these schedule changes

would have a very small effect (less than 5 percent) on the level or timing of employment under the various alternatives. Because this is well

within the accuracy of the socioeconomic modeling, the modeling was not revised.

The Final EIS

includes a new alternative that was not analyzed in detail in the Draft EIS. This alternative, the Ex Situ/In Situ Combination 2

alternative, would have lower overall employment levels than the Ex Situ/In Situ Combination 1 alternative that was analyzed in detail in the Draft

EIS. However, the timing of the employment peaks under the Ex Situ/In Situ Contamination 2 alternative, as well as the duration of

its construction and operations phases, would be similar to the Ex Situ/In Situ Combination 1 alternative. Data are provided in

this appendix for peak and average employment levels for the Ex Situ/In Situ Combination 2 alternative. However, no socioeconomic

modeling has been performed because of its similarity to the Ex Situ/In Situ Combination 1 alternative.

H.1.1 DEVELOPMENT OF THE BASELINE ECONOMIC ESTIMATE

This section describes the assumptions, data, and methodology used to develop the baseline estimate of future economic activity in the Richland, Kennewick, and Pasco (also called the Tri-Cities) MSA. This estimate was used to analyze the socioeconomic impacts of the EIS alternatives.

The socioeconomic impact analysis compares the impacts of the EIS alternatives to an estimate of future economic conditions in the Tri-Cities area, based on Hanford Site employment in the absence of any

TWRS activities (except for a phased shutdown of routine tank farm operations). The scenario for future Hanford Site employment that provided the baseline for the impact analysis was calculated using the following method:

- **The latest available estimate of total Hanford Site employment was obtained from Hanford Site facility planning personnel (Daly 1995). This estimate assumed implementing the TWRS program as defined by the Hanford Federal Facility Agreement and Consent Order (Tri-Party Agreement) (Ecology et al. 1994).**

- **Labor requirements were estimated over time to implement the TWRS programs as defined in the Tri-Party Agreement, based on engineering data provided by the Hanford Site Management and Operations contractor (WHC 1995a). The engineering data were provided for total labor hours by phase of the activity. The EIS contractor then adjusted the labor hours to reflect the final alternatives selected for analysis in the EIS and to ensure consistency in the methodology used to develop labor estimates among the alternatives (Jacobs 1996). These data were then provided for**

inclusion as inputs into the socioeconomic modeling.

- # The labor requirements for the TWRS program were then subtracted from the overall estimate of Hanford Site employment to derive a calculational baseline for Hanford Site employment that excludes remediation of the tank waste.

This calculational baseline for Hanford Site employment (total employment without TWRS employment) then was used in an econometric forecasting model to analyze the socioeconomic impacts of

the various EIS alternatives. Figure H.1.1.1 shows both the estimate of total Site employment and the calculational baseline of total Site employment without TWRS employment. All figures and tables in this appendix are provided after page H-1 5 .

Assumptions incorporated into the impact analysis included the following:

- **The latest available estimated total Hanford Site employment (including potential TWRS activities as defined in the Tri-Party Agreement) was**

derived from data for selected years between 1994 and 2025. The intervening years were estimated using straight-line interpolation. For the years subsequent to 2025, a straight-line extrapolation was used, with 2040 as the end year.

- **The latest available estimated total Hanford Site employment incorporated planned restructuring of the Hanford Site labor force, including early retirements and reductions in force, as well as new hires expected in 1995 for the Hanford Site environmental restoration contractor, and for the U.S. Department of Energy (DOE),**

Richland Operations Office. Because plans for labor force restructuring and new hires are under constant review, these estimates are imprecise but are the best currently available.

- # The latest available total Hanford Site labor employment estimate includes other (non-TWRS) environmental cleanup and restoration activities, operations and maintenance, research and development (including the Environmental and Molecular Sciences Laboratory and the Laser Interferometer Gravitational Wave Observatory), and facilities management personnel required to

operate and maintain the Hanford Site.

- **The data on the proposed TWRS program, as defined in the Tri-Party Agreement, provided by the Hanford Site Management and Operations contractor and the TWRS EIS contractor were used in the following manner. Annual employment data were developed based on engineering projections that allocated estimated labor requirements over the different phases of the project. The annual labor requirements data were then interpolated (or assigned intermediate values) to provide**

quarterly data, as required by the regression model, to be used to estimate impacts. Because the total Hanford Site employment data were estimated using smoothed interpolations, the TWRS Tri-Party Agreement labor requirements estimates also were smoothed using a 30-quarter moving average before subtracting them from the total Hanford Site employment estimates to obtain the calculational baseline employment estimates. This smoothing was done to maintain consistency between the two data series. Without smoothing the data, the annual fluctuations in the TWRS

Tri-Party Agreement data would have been transferred to the calculational baseline estimate, creating a misleading result. However, the smoothed TWRS Tri-Party Agreement data were used only to estimate calculational baseline employment. The socioeconomic impact analysis of the EIS alternatives used unsmoothed data added to the calculational baseline. The calculational baseline estimate used to construct estimates of total Hanford Site employment for each of the proposed EIS alternatives is described in Section H.3.1.

- **Routine operations at the tank farms were included in the latest available total Hanford Site employment estimate and in the estimated labor requirements for the TWRS Tri-Party Agreement labor estimate. As envisioned in the Tri-Party Agreement, tank farm routine operations would be phased out over time as remediation occurs. Estimates for employment in routine operations (including phaseouts over time) were incorporated into the labor requirements for the other TWRS EIS alternatives as described in Section H.3.1. The inclusion of the routine operations labor estimate in**

the calculational baseline was factored into the labor estimates for each of the alternatives. Routine operations were estimated to require 1,016 full-time equivalent employees. In the calculational baseline, it was assumed that the routine operation activities would phaseout beginning in 2005, with an end to routine operations in 2029. For alternatives with routine operations extending at current levels beyond 2005, the labor required to maintain the 1,016 employment level was added to the alternative labor estimates. This was the case for the No Action, Long-Term Management, and In Situ Fill

and Cap alternatives. For other alternatives that ended routine operations prior to 2029, the appropriate level of employment was subtracted for the labor estimate. This was the case for the In Situ Vitrification, Ex Situ/In Situ Combination 1, Ex Situ/In Situ Contamination 2, and Phased Implementation alternatives.

The calculational baseline estimate of Hanford Site employment is used only to provide a basis for analyzing the impacts of the proposed EIS alternatives. These impacts are measured in terms of percentage

changes from the calculational baseline. Neither the calculational baseline nor the impact analysis itself is intended to be a precise forecast of future economic conditions in the Tri-Cities MSA. Any forecast that extends over 40 years can only project current trends and is subject to unpredictable changes in future economic conditions. The Tri-Cities is in the early stages of an economic transition as Site employment decreases. There are currently little definitive data to indicate how successful attempts to diversify the local economy will be in reducing dependence on the Hanford Site, the area's largest single

employer. Likewise, any estimates of future Hanford Site employment under any scenario must be considered as estimates rather than definitive data. The calculational baseline estimate, however, provides a consistent projection of one possible path for Hanford Site employment that can be used as the basis for analyzing and comparing the impacts of the EIS alternatives. Changes in future Hanford Site employment or future Tri-City MSA employment would affect the amount of population growth, taxable sales growth, housing price changes, and other socioeconomic factors analyzed in the

EIS. However, such future employment changes would affect all EIS alternatives equally and thus would not affect the comparison of the relative impacts of the alternatives.

H.2.0 ECONOMETRIC FORECASTING MODEL METHODOLOGY

Quantitative projections of the impacts of the TWRS EIS alternatives on nonfarm employment, population,

housing prices, and taxable retail trade were obtained by regression analysis, using Hanford Site employment as the

key independent variable. The regression analysis used data from historical experience to determine the statistical

relationship between Hanford Site employment and total Tri-Cities MSA nonfarm employment (1987 to 1993), and the

statistical relationship between nonfarm employment and taxable retail sales (1987 to 1993), population (1980 to 1993), and

housing market conditions (1980 to 1993). These statistical relationships provide information on the potential impacts

# of future changes in Hanford Site employment on retail sales, population, and housing market conditions.

Analyzing the impacts of the EIS alternatives required specific estimates of labor hours for implementing each alternative. In

each case, these labor hours were estimated based on cost and labor input data supplied by the Hanford Site Management and

Operations contractor (WHC 1995a, c, e, f, g, h, i, j, n) and by the TWRS EIS contractor (Jacobs 1996). The data first were

estimated as annual average full-time equivalent employees, then interpolated to obtain quarterly full-time

equivalent employees (at annual rates). The labor estimates for the EIS alternatives then were added to the calculational

baseline estimate of total Hanford Site employment to obtain total Hanford Site employment estimates under each alternative.

The estimates of total Hanford Site employment associated with the EIS alternatives then were used to estimate impacts on nonfarm

employment in the Tri-Cities MSA. Because Hanford Site activities do not impact farm employment, the analysis addresses nonfarm

employment only. Nonfarm employment then was used to estimate impacts on taxable retail sales and population.

Population was used to estimate impacts on housing prices.

The econometric model used to estimate impacts

accounts for the "multiplier effect" of Hanford Site jobs on the Tri-Cities economy. For each new job at the Hanford Site,

it was estimated that approximately 2.4 jobs would be created in the nonfarm employment sector. These jobs,

as well as the new Hanford Site jobs, then were used in estimating other impacts, including taxable retail sales, population, and housing

market conditions. This 2.4 multiplier is in reasonably close agreement with employment multipliers used in other recent

Hanford Site National Environmental Policy Act (NEPA) documents. For example, the Safe Interim Storage of

Hanford's Tank Waste Final EIS (DOE 1995i) used a 2.2 multiplier based on input/output analysis by the Pacific Northwest

National Laboratory. However, the model used for the TWRS is based on historical data for the Tri-Cities

through the end of 1993, whereas the Pacific Northwest National Laboratory multiplier was developed in the

late 1980's and is considered to be less representative of current economic conditions. These two models are the only known

comprehensive economic models that were developed by analyzing the local economy.

All equations are

linear and were estimated using ordinary least squares. The following sections of this appendix (H.2.1 through H.2.4) document

the regression equations used in the quantitative assessments.

H.2.1 EMPLOYMENT

The regression equation for total Tri-Cities MSA nonfarm employment uses quarterly data from the third quarter of 1987 to the fourth quarter of 1993 and has the following

explanatory variables:

X1 = Hanford Site employment (full-time equivalent employees);
X2 = Time trend;
X3 = First quarter dummy variable;
X4 = Lagged Hanford Site employment (one year or four quarters); and
Y1 = Nonfarm employment.

The time trend starts at one for the third quarter of 1987. Data on Hanford Site employment were obtained from the DOE Richland Operations Office. Data on Tri-Cities MSA employment were obtained from

the Washington State Department of Employment Security (WSDES 1993b). Table H.2.1.1 shows the data used to estimate the regression equation. The T-value for each estimated parameter (a measure of the statistical significance of the estimated parameter, where a T-value greater than two means that there is a high degree of confidence that the true value of the parameter is different than zero) is shown in parentheses. The adjusted R-squared value (a measure of the goodness-of-fit of the estimated equation) is shown immediately after the equation. An adjusted R-squared value of 1.0

indicates a perfect fit.

The estimated equation for employment is:

Y1 = 36998.466489 + 2.438843 X1 + 209.789246 X2 - 1500.74503 X3 - 0.822646 X4

(4.574603) (3.103108) (1.039399) (-4.539982) (-4.440990)

Adjusted R-squared: 0.986

Note:

. = Multiplied by

H.2.2 TAXABLE RETAIL SALES

The regression equation for taxable retail sales uses quarterly data from the third quarter of 1987 to the third quarter of 1993 (the latest data available). The equation has the following explanatory variables:

X5 = Time trend;
X6 = Quarterly nonfarm employment at annual rates;
X7 = First quarter dummy variable;
X8 = Fourth quarter dummy variable; and
Y2 = Taxable retail sales.

The data on taxable retail sales were obtained from the Washington State

Department of Revenue (WSDR 1993). Table H.2.2.1 shows the data used to estimate the regression equation.

The equation for taxable retail sales is:

Y2 = -68.899165 + 5.089547 X5 + 0.005126 X6 - 37.779538 X7 + 0.687021 X8

(-0.613913) (3.652568) (2.471805) (-4.976665) (0.108059)

Adjusted R-squared: 0.964

Note:

. = Multiplied by

H.2.3 POPULATION

The regression equation for population in the Tri-Cities MSA used annual data on population for 1980 to 1993. The explanatory variables are:

X14 = Time trend;
X15 = Annual average nonfarm employment, with a lag of 1 year; and
Y3 = Population.

The time trend starts at one for 1980, although 1980 is not used in the regression because lagged employment is used. The data on population comes from the 1980 and

1990 U.S. Census (DOC 1991) and the Washington State Department of Financial Management (WSDFM 1987-95) for years other than 1980 and 1990. Table H.2.3.1 shows the data used in the regression analysis.

The equation for population is:

Y3 = 58107.265102 + 358.944822 X14 + 1.465489 X15
(3.805755) (1.160945) (5.370630)
Adjusted R-squared: 0.764
Note:
. = Multiplied by

H.2.4 AVERAGE HOME

PRICES

The regression equation for the average home price in the Tri-Cities MSA used annual data for 1980 to 1993 (HBA 1994). The explanatory variables are:

X9 = Time trend;
X10 = Population; and
Y4 = Average home price.

Data on home prices were obtained from the Tri-Cities Association of Realtors (TAR 1995). Table H.2.4.1 shows the data used to estimate the equation.

The equation for the average home price is:

$$Y4 = -176.372436 + 0.508830\ X9 + 0.001653\ X10$$

(-7.901429) (1.755588) (10.435336)

Adjusted R-squared: 0.926

Note:

. = Multiplied by

H.3.0 TWRS EIS ALTERNATIVES IMPACT

PROJECTIONS

For each EIS alternative, the economic impact estimates were made using the following four

steps.

Estimates of total Hanford Site employment under the alternative were used to estimate

quarterly nonfarm employment. Estimated quarterly nonfarm employment was used to estimate

quarterly taxable retail sales. Quarterly sales were summed for each year to yield estimated annual taxable retail sales.

Quarterly sales estimates of nonfarm employment for each year were averaged to estimate the average annual

employment for that year. Average annual employment was lagged 1 year and then used to estimate population.

Annual population estimates were used to estimate average annual home prices.

H.3.1 HANFORD SITE EMPLOYMENT PROJECTIONS

This section provides detail on the development of the employment estimates for the EIS alternatives. For each alternative, the annual average employment was estimated for each phase of activity based on engineering data and cost estimates provided by the Hanford Site Management and Operations contractor (WHCa, c, e, f, g, h, i, j, n) and the TWRS EIS contractor (Jacobs 1996).

Employment for each phase of each EIS alternative was divided into three phases for purposes of this analysis. These phases are 1) construction of

facilities; 2) facilities operations; and 3) post remediation, including decontamination and decommissioning (D&D) of remediation facilities and monitoring and maintenance (M&M) activities as applicable. Activities for each phase then were divided into waste retrieval, waste transfer, and waste processing activities. For analytical purposes, the estimates of waste retrieval and processing activities were aggregated into the construction, operations, and post-remediation phases. Each alternative would also involve routine operations of the tank farms that, for all alternatives except No Action and

Long-Term Management, would be phased out over time as remediation occurs.

Once total annual average employment for each alternative was derived by combining the annual data for the various phases, the data were converted to quarterly employment by straight line interpolation. Interpolation was used to build ramp-up and ramp-down periods into the quarterly Hanford Site employment data, which more accurately reflect the process of increasing or decreasing staffing levels for large-scale projects. However, because of

the interpolations, annual average Hanford Site employment data as used in the forecasts and reported in Tables H.3.2.1 through H.3.2.3 will differ slightly from the annual employment data reported in Tables H.3.1.1 through H.3.1.10. Then, the quarterly data for the alternatives were added to the calculational baseline of quarterly average total Hanford Site employment. The resulting estimate of total Hanford Site employment under each alternative then was input to the forecasting model to produce the socioeconomic impact analysis for the Tri-Cities MSA.

No Action Alternative (Tank Waste)

The No Action alternative would have one phase: routine tank farm operations. Figure H.3.1.1 and Table H.3.1.1 show the number of potential full-time equivalent employees by phase under this alternative. The routine tank farm operations phase assumes that routine operations would be maintained at the TWRS program Tri-Party Agreement level through 2005. After 2005, the TWRS program Tri-Party Agreement would involve a steady phaseout of routine operations, while the No Action alternative would maintain routine

operations staffing at the 2005 level of just over 1,000 full-time equivalent employees. The difference between routine operations employment under the No Action alternative and under the TWRS program Tri-Party Agreement was used to calculate total employment for the No Action alternative. Use of the TWRS program Tri-Party Agreement routine operations estimates in the baseline estimate resulted in the need to add employment to the No Action alternative estimates from 2005 through 2029. The jobs were added to maintain employment levels at 1,016 for routine operations.

Long-Term Management Alternative

The Long-Term Management alternative would have two phases: 1) routine tank farm operations; and 2) tank replacement (which would include waste retrieval and transfer activities as well as new tank construction).

The routine operations phase of the Long-Term Management alternative is identical to the routine operations phase for the No Action alternative. The Long-Term Management alternative assumes that the double-shell waste tanks would be replaced every 50 years. The data in Table H.3.1.2 and Figure H.3.1.2 show one such replacement cycle in the 2030's. Future tank replacements would occur beyond the 2040 time frame for the analysis in this EIS.

In Situ Fill and Cap Alternative

This alternative would involve neither a waste retrieval and transfer or a D&D phase. The phases for the In Situ Fill and Cap alternative would include:

- Construction (install fill equipment);
- Fill and cap operations;

Post remediation - M&M and tank closure; and

- **Routine tank farms operations.**

Employment under this alternative would be low; a maximum change from the calculational baseline of less than 150 in the peak year, which is approximately 1 percent of the calculational baseline total Hanford Site employment. Figure H.3.1.3 and Table H.3.1.3 show the number of full-time equivalent employees by phase for the In Situ Fill and Cap alternative. Under this alternative, routine tank farm operations would differ greatly from the TWRS

program Tri-Party Agreement estimate. The In Situ Fill and Cap alternative would result in a faster completion of tank waste remediation, which would result in routine operations being phased out sooner. The calculation of Hanford Site employment under the In Situ Fill and Cap alternative includes the difference between routine tank farm operations under the TWRS program defined in the Tri-Party Agreement and routine operations under the In Situ Fill and Cap alternative. This difference would represent a reduction in Hanford Site employment, as compared to the

baseline. Because of this difference, the estimate of employment impacts presented in Figure H.3.1.3 and Table H.3.1.3 show a negative estimate of total employment under the alternative from 2023 through 2030. This comparison only represents a negative number of jobs compared to the baseline estimate.

In Situ Vitrification Alternative

The In Situ Vitrification alternative would not involve waste retrieval and transfer but would involve a relatively minor D&D phase. The operations phases for this alternative would

include:

- Vitrification facilities construction;
- Vitrification operations;
- Post-remediation activities - M&M, D&D, and tank closure; and
- Routine tank farm operations.

Figure H.3.1.4 and Table H.3.1.4 show the number of full-time equivalent employees by phase for the In Situ Vitrification alternative.

Ex Situ Intermediate Separations Alternative

The Ex Situ Intermediate Separation s alternative would involve the

following phases:

- **Waste retrieval and transfer - construction;**
- **Waste retrieval and transfer - operations;**
- **Waste retrieval and transfer - D&D;**
- **Waste processing - construction;**
- **Waste processing - operations;**
- **Post remediation - M&M, D&D, and tank closure; and**
- **Routine tank farm operations.**

Figure H.3.1.5 and Table H.3.1.5 show projected employment for each phase of the alternative. The routine operations phase is identical to the

routine operations estimate for the TWRS program as defined in the Tri-Party Agreement, and it is therefore currently built into the baseline projection as part of the current forecast of Hanford Site employment. Because of this, routine operations were not separately incorporated into the calculated Hanford Site employment for this alternative. Construction employment for both waste retrieval and transfer and for the vitrification facilities would peak in the year 2000 and decline sharply through 2010. Operations employment would begin in 1997, climb steadily from 2001 through

2003, level off for several years, and then climb sharply in 2009 when full-scale waste processing operations would begin. Operations employment would drop off sharply in 2019, at which point post-remediation activities would be conducted.

Ex Situ No Separations Alternative

This alternative's breakdown by phase is the same as for the Ex Situ Intermediate Separations alternative. Figure H.3.1.6 and Table H.3.1.6 show employment for the Ex Situ No Separations alternative by construction, operations, and post-

remediation phases. The data show a large spike in construction activity in the period 1997 to 2003. Not only would the level of employment for construction reach almost 4,500 jobs in 2000, but the period of construction activity would be very short, with construction jobs falling to 3,000 in 2001 and below 1,000 by 2003.

Ex Situ Extensive Separations Alternative

Employment would involve the same phases for this alternative as for the Ex Situ Intermediate Separations alternative. As shown in Figure

H.3.1.7 and Table H.3.1.7, employment under the alternative would result in two spikes in construction activity. Both spikes would occur during construction of the waste processing facilities. The boom-bust cycle reflected by the two spikes would result in substantial economic impacts because of the transient nature of crews working on large construction projects. The Tri-Cities MSA experienced similar conditions in the early 1980's with the Washington Public Supply System nuclear project (as noted in Section 4.6).

Ex Situ/In Situ Combination 1 Alternative

This alternative is a combination of the In Situ Fill and Cap alternative and the Ex Situ Extensive Separations alternative. The waste from approximately 70 tanks would be retrieved, transferred, and processed as described for the Ex Situ Intermediate Separations alternative, with the remaining tanks undergoing fill and cap construction and operations activities as described for the In Situ Fill and Cap alternative. The breakdown by phases for Ex Situ/In Situ Combination 1 alternative

would be as follows:

In Situ Fill and Cap Component

- Construction (install fill equipment)
- Waste retrieval and transfer - construction
- Post remediation M&M, D&D; and tank closure; and
- Waste retrieval and transfer - D&D
- Waste processing - operations
- Routine tank farm operations

Ex Situ Intermediate Separations Component

- Fill and cap operations
- Waste retrieval and transfer - operations
- Routine tank farm operations
- Waste processing - construction
- Post remediation M&M, D&D, and tank closure; and

Figure H.3.1.8 and Table H.3.1.8 show estimated employment under the Ex Situ/In Situ Combination 1 alternative by project phase. Construction activity, including both waste retrieval and transfer and waste processing facilities, would peak in 2000, and then begin a steady decrease through 2010. After several years of level employment, construction activity then would fall

steadily until it ends in 2018. Operations, including both transfer and retrieval and waste processing, would begin to increase in the late 1990's with a fairly level period between 2003 and 2009. This would be followed by a large increase to a peak level in 2010, when waste processing would reach its full operational status. After 2018, operations would decline sharply when the post-remediation activity (including tank closure and D&D of facilities) would occur. Except for minimal M&M activities, total Hanford Site employment for the Ex Situ/In Situ Combination 1 alternative and the calculational

baseline would converge by 2030.

Ex Situ/In Situ Combination 2 Alternative

This alternative is very similar to the Ex Situ/In Situ Combination 1 alternative except that wastes would be retrieved from 25 tanks rather than from approximately 70 tanks under the Ex Situ/In Situ Combination 1 alternative. The remainder of the 177 tanks would undergo fill and cap construction and operations activities as described for the Ex Situ/In Situ Combination 1 alternative. The primary difference

between the two Ex Situ/In Situ Combination alternatives is that the Ex Situ/In Situ Combination 2 alternative would involve scaled-down waste retrieval, waste transfer, and waste processing activities, which include pretreatment, LAW processing, high-level waste (HLW) processing, LAW vaults, and HLW temporary storage. This smaller scale of operations is because there would be fewer tanks from which the waste would be retrieved and a smaller volume of waste to be processed. The smaller scale of operations generally would result in lower levels of employment to implement the Ex

Situ/In Situ Combination 2 alternative than would be required for the Ex Situ/In Situ Combination 1 alternative, particularly during the operations phase. However, the timing of the employment peaks and the nature and duration of the various phases of activity would be similar between these two alternatives.

Peak construction phase employment under the Ex Situ/In Situ Combination 2 alternative would occur in the year 2001 at about 2,200 workers. Over the 14-year construction period, employment would average about 1,400 workers.

Over the 35-year operating period under this alternative, there would be a broad peak employment period from the year 2008 to 2019. During this peak period, employment would average approximately 750 workers. Over the entire 35-year operations period, employment would average about 430 workers.

As mentioned in Section H.1.0, no detailed year-by-year employment data were generated for the Ex Situ/In Situ Combination 2 alternative, nor was any socioeconomic modeling performed to assess its impacts. Thus, this appendix contains no detailed

data tables or graphics for this alternative, either describing employment under the alternative or evaluating its impacts on overall Tri-Cities nonfarm employment, population, taxable retail sales, or housing prices. The lower levels of employment under this alternative compared to the Ex Situ/In Situ Combination 1 alternative would result in smaller socioeconomic impacts on the Tri-Cities area.

Phased Implementation Alternative

The Phased Implementation alternative differs from the other

alternatives, and this difference is reflected in the economic impact analysis. Phased Implementation would involve a demonstration phase (Phase 1) and a full-scale treatment phase (Phase 2). The demonstration phase would involve two combined separations and LAW facilities and one separations and HLW vitrification facility. After completing the demonstration phase, the demonstration plants would be shut down and two LAW vitrification facilities and one HLW vitrification facility would be built, together with waste retrieval and transfer facilities. The full-scale facilities would operate

through 2025. The economic impact analysis is divided into two parts; Phase 1 covers the demonstration phase only, and the total alternative covers the entire Phased Implementation alternative.

Labor force requirements for the Phased Implementation alternative were based on the Ex Situ Intermediate Separations alternative, scaled for the reduced size of the facilities, and include construction, operation, and post-remediation labor force for the two plants. In addition, there was a further 15 percent reduction in labor force requirements based on an improved overall efficiency in operating personnel operations during the first phase.

Phase 1

Phase 1 of the Phased Implementation alternative would consist of construction, operations, and post remediation (including D&D).

Because this alternative would involve a reduced-scale demonstration and terminate in 201 2 after processing only a portion of the tank waste, routine operations are assumed to be the same as under the calculational

baseline and are not separately identified. Also, M&M activities are not included because of the limited duration of the alternative. A small number of workers would be involved in transferring waste from the tanks to the treatment facility and are included in the operations phase labor force projections. Figure H.3.1.9 and Table H.3.1.9 show the labor force projections for each element of the alternative. Since publication of the Draft EIS, changes in Phase 1 of this alternative resulted in estimated employment levels that are within 2 percent of the levels presented in the Draft EIS. Thus, socioeconomic

impacts for Phase 1 would be very similar to those presented in the Draft EIS.

Total Alternative

The total Phased Implementation alternative would consist of construction, operations, post remediation (including D&D and M&M), and routine operations.

Labor requirements for the total Phased Implementation alternative track the Phase 1 labor requirements through 2003. Construction of waste retrieval and transfer facilities for

Phase 2 would begin in 2004. Construction of the waste treatment facility would begin in 2005. Operation of the Phase 2 waste retrieval and treatment facilities would extend through 2025. D&D of the waste retrieval and transfer facilities would begin in 2015 and extend through 2027, while D&D of the waste treatment facilities would begin in 2022 and extend through 2030. Tank closure would begin in 2016 and conclude in 2039. Routine operations virtually would be the same as in the calculational baseline, except for some accelerated reduction in the labor force after 2020. Figure

H.3.1.10 and Table H.3.1.10 show the labor force projections for each phase.

Capsule Alternatives

The maximum number of employees that would be involved in implementing any of the capsule alternatives would be 47 employees in the peak year. This low level of employment will not have a measurable impact on current and future socioeconomic conditions. For this reason, the socioeconomic impacts of capsule alternatives were not modeled. However, where appropriate, data regarding employment under the alternatives are presented in Section 5.6.

H.3.2 DATA TABLES FOR IMPACTS OF TWRS EIS ALTERNATIVES

The annual impacts of the EIS alternatives are presented in the following data tables.

Data regarding Hanford Site employment are presented in Tables H.3.2.1, H.3.2.2, and H.3.2.3. Tri-Cities nonfarm employment data are presented in Tables H.3.2.4, H.3.2.5, and H.3.2.6. Data regarding Tri-Cities

population are presented in Tables H.3.2.7, H.3.2.8, and H.3.2.9. Tri-Cities taxable retail sales data are presented in Tables H.3.2.10, H.3.2.11, and H.3.2.12 and data regarding Tri-Cities housing prices are presented in Tables H.3.2.13, H.3.2.14, and H.3.2.15.

For all tables presented in this Appendix, routine operations are those in addition to routine operations labor requirements under the TWRS program Tri-Party Agreement estimate, which includes approximately 1,000 employees for routine operations through 2005 and

a phaseout of employment through 2029. The employment estimate assumes employment for routine operations would continue at 1995 levels through 2040. Negative numbers in Tables H.3.1.3 to H.3.1.10 and H.3.2.1 to H.3.2.15 result from the phaseout of routine operations on an earlier schedule than included in the TWRS program Tri-Party Agreement estimates.

I.1.0 INTRODUCTION

This appendix describes the environmental setting for the proposed Tank Waste Remediation System (TWRS) activities at the Hanford Site. By describing the environmental conditions that could be potentially impacted by TWRS activities, this appendix provides the context and basis for analyzing the impacts of the Environmental Impact Statement (EIS) alternatives. Data to support comparisons between the potential impacts of the various EIS alternatives are also provided within this appendix. Existing conditions are discussed for all aspects of the environment (soil, groundwater, air, plant and animal species habitats, socioeconomic conditions, biological and ecological resources, cultural resources, land use, visual resources, noise, and transportation). Additional details on existing environmental conditions can be found in the Hanford Site National Environmental Policy Act (NEPA) Characterization Report (Cushing 1994 and 1995 , Neitzel 1996), the Hanford Environmental Report for Calendar Year s 1994 and 1995 (PNL 1995 and 1996), and in other references cited within the text. Information on the potential TWRS borrow sites was obtained largely from the Site Evaluation Report for Candidate Basalt Quarry Sites (Duranceau 1995).

The Hanford Site is in the semi-arid region of the Columbia Plateau in southeastern Washington State (Figure I.1.0.1). The Hanford Site occupies about 1,450 square kilometers (km^2) (560 square miles [mi^2]) of shrub and grasslands just north of Richland, Washington. The majority of this large land area, with restricted public access, provides a buffer to the smaller areas within the Hanford Site historically used for producing nuclear materials, waste storage, and waste disposal. About 6 percent of the land has been disturbed and is actively used. The Hanford Site extends approximately 77 kilometers (km) (48 miles [mi]) north to south and 61 km (38 mi) east to west.

The Columbia River flows through the northern part of the Hanford Site, turning south to form part of its eastern boundary. The Yakima River runs along part of the southern boundary and joins the Columbia River at the city of Richland. Adjoining lands to the west, north, and east are principally range and agricultural land. The cities of Richland, Kennewick, and Pasco (also known as the Tri-Cities) comprise the nearest population centers and are located southeast of the Site.

I.1.1 GEOLOGY AND SOIL

Geologic information on the Hanford Site (Figure I.1.1.1) has been collected in connection with a variety of Site activities. Reports by Delaney (Delaney et al. 1991), Reidel (Reidel et al. 1992), and Cushing (Cushing 1994), summarizing the information collected during many of these activities, are the primary basis for the following overview of the Hanford Site's subsurface environment.

The geology of the Hanford Site forms the framework for the Site's groundwater and surface water resources. Of particular relevance are 1) the topography, which impacts surface water flows and infiltration; 2) the vadose zone, because of potential impacts associated with releases during proposed TWRS activities; and 3) the saturated sediments beneath the vadose zone that form the unconfined aquifer, because of potential impacts from releases that pass through the vadose zone from proposed TWRS activities.

Figure I.1.0.1 Hanford Site and Vicinity

Figure I.1.1.1 Geographic Setting and General Structural Geology of the Pasco Basin and Hanford Site

The geology and water resources sections focus primarily on conditions in the 200 Areas, where the tank waste and strontium (Sr) and cesium (Cs) capsules are located and where virtually all TWRS facilities, except for three potential borrow sites, would be located under any of the EIS alternatives. The potential Pit 30 borrow site, a possible source of sand and gravel, is located between the 200 East and 200 West Areas. The geologic setting of the Pit 30 area is the same as is described for the 200 Areas. The potential McGee Ranch and Vernita Quarry borrow sites, possible sources of silt (McGee) and basalt (Vernita), are located approximately 6 km (4 mi) north and west of the 200 West Area.

Geologic conditions for the McGee Ranch and Vernita Quarry areas are briefly described in the following sections.

I.1.1.1 Topography and Geomorphology

The existing tank farms are on a broad flat area called the Central Plateau, which overlies an alluvial terrace (Figure I.1.1.1). The Central Plateau is in a portion of the Pasco Basin, a topographic, structural depression in the southwest corner of the Columbia Basin physiographic subprovince. This subprovince is characterized by generally low-relief hills with deeply incised river drainage. The Central Plateau's elevation is approximately 200 meters (m) (650 feet [ft]) to 230 m (750 ft) above sea level. The Plateau decreases in elevation to the north, northwest, and east toward the Columbia River. Plateau escarpments have elevation changes of 15 m (50 ft) to 30 m (100 ft). The proposed Vernita Quarry and McGee Ranch borrow sites are located to the west of the northern portions of the Central Plateau.

The Pasco Basin is an area of generally low relief ranging from 120 m (390 ft) above mean sea level at the Columbia River level, to 230 m (750 ft) above mean sea level in the vicinity of the TWRS sites in the 200 East Area. The Pasco Basin is bounded on the north by the Saddle Mountains; on the west by Umtanum Ridge, Yakima Ridge, and the Rattlesnake Hills; on the south by Rattlesnake Mountain and the Rattlesnake Hills; and on the east by the Palouse Slope (Figure I.1.1.1).

Surface topography at the Hanford Site is the result of the uplift of anticlinal ridges, Pleistocene cataclysmic flooding, Holocene eolian activity, and landslides (Delaney et al. 1991). Uplift of the ridges began in the Miocene Epoch, concurrent with the eruption of the flood basalts and continues to present. Cataclysmic flooding occurred when glacial ice dams in western Montana and northern Idaho were breached, allowing large volumes of water to spill across eastern and central Washington State. Much of the landscape in the path of the floodwater was stripped of sediments and basalt bedrock was scoured, forming scabland topography (elevated areas underlain by flat-lying basalt flows that generally exhibit deep, dry channels scoured into the surface). The last major flood occurred approximately 13,000 years ago during the late Pleistocene Epoch.

Braided flood channels with giant water current ripples, bergmounds (hummocky areas where grounded icebergs melted), and giant flood bars are among the landforms created by flooding that are apparent on the Hanford Site. Since the end of the Pleistocene Epoch, winds have reworked the flood sediments locally, depositing sand dunes in the lower elevations and loess (wind-blown silt) around the margins of the Pasco Basin. Sand dunes generally have been stabilized by anchoring vegetation, except in localized areas where they have been reactivated around disturbed vegetation and within the barchan dune complex in the west-central portion of the Site.

Observed landslide activity in the area is generally limited to the White Bluffs area east of the Hanford Site and the Rattlesnake Hills south of the Hanford Site. No landslide activity has been observed in the vicinity of the tank farms or the TWRS sites in the 200 East Area.

I.1.2 GEOLOGIC STRUCTURE

The Hanford Site lies in the Pasco Basin near the eastern limit of the Yakima Fold Belt. The Pasco Basin is a structural depression bounded by anticlinal ridges on the north, west, and south and a monocline on the east (Figure I.1.1.1). The Pasco Basin is divided by the Gable Mountain anticline in the Wahluke syncline to the north and the Cold Creek syncline to the south. Geologic materials that include basalts and sediments thicken into the Pasco Basin and generally reach maximum thickness in the Cold Creek syncline (Delaney et al.1991).

The 200 Areas are situated between the Gable Mountain anticline and the Cold Creek syncline (Figure I.1.1.1). The Gable Mountain anticline is of particular importance to groundwater flow in the unconfined aquifer. This anticline consists of a series of southeast to northwest trending folds (Trent 1992b). Portions of the Gable Mountain anticline have been uplifted high enough that basalt is above the current water table. These basalts have a low hydraulic conductivity and act as a barrier to horizontal groundwater flow in the unconfined aquifer.

The uppermost basalt underlying the 200 Areas is the Elephant Mountain Member of the Saddle Mountain Basalt Formation (Trent 1992a and b). Two adjacent boreholes north of the 200 East Area (6-53-55 and 6-55-55) encountered the Rattlesnake Ridge interbed of the Ellensburg Formation (Trent 1992b), but the Elephant Mountain Member basalt flow was absent. The absence of the Elephant Mountain Member basalt flow is referred to as a "window" (Trent 1992a and b) and is probably erosional, formed during the Pleistocene cataclysmic flooding. There is no evidence for other substantial erosion into the top of the Elephant Mountain Member and no indication of erosional windows through the basalt into the underlying Rattlesnake Ridge interbed in the 200 West Area (Trent 1992a).

I.1.3 STRATIGRAPHY AND LITHOLOGY

A generalized stratigraphic column illustrating the nomenclature for the formations that underlie the Hanford Site is provided in Figures I.1.3.1 and I.1.3.2.

I.1.3.1 Columbia River Basalt Group

The Columbia River Basalt Group, which is a sequence of basaltic rock found typically on the ocean floor, erupted as basalt flows between 6 and 17 million years ago. These flows cover an area of more than 163,000 km^2(63,000 mi^2) and have an estimated area of 174,000 km^2(40,800 mi^2). The thickness of basalt accumulations in the Pasco Basin is in excess of 3,000 m (10,000 ft) (Delaney et al. 1991). The Columbia River Basalt Group is divided into five formations (from oldest to youngest): Imnaha Basalt, Picture Gorge Basalt, Grande Ronde Basalt, Wanapum Basalt, and Saddle Mountains Basalt. Only the Grande Ronde Basalt, Wanapum Basalt, and Saddle Mountains Basalt are exposed on the Hanford Site. The Elephant Mountain member of the Saddle Mountains Basalt forms the uppermost basalt unit beneath most of the Hanford Site, except near the 300 Area where the Ice Harbor member is present, and north of the Central Plateau near Gable Gap where the Saddle Mountains Basalt has been eroded down to the Umatilla member.

Figure I.1.3.1 Generalized Stratigraphy of the Hanford Site

Figure I.1.3.2 Stratigraphic Column for the Hanford Site Showing Nomenclature From Previous Investigations by Various Authors

I.1.3.2 Ellensburg Formation

The Ellensburg Formation consists of a series of sedimentary units that are interbedded between many of the basalt flows of the Columbia River Basalt Group. The Ellensburg Formation generally displays volcanic characteristics produced by volcanic events in the Cascade Range, and silicic characteristics derived from erosion of the Rocky Mountains. At the Hanford Site, the Ellensburg Formation consists of a mix of sediments deposited by the ancestral Clearwater and Columbia Rivers (Delaney et al. 1991). The three uppermost units of the Ellensburg Formation at the Site are the Levey Interbed, confined to the vicinity of the 300 Area, and the Rattlesnake Ridge and Selah interbeds, found beneath most of the Hanford Site (Delaney et al. 1991).

I.1.3.3 Suprabasalt Sediments

The suprabasalt sediments are a sedimentary sequence overlying the basalts at the Site and include the Ringold and Hanford formations. These sediments are up to approximately 230 m (750 ft) thick in the west-central Cold Creek syncline and pinch-out against the Saddle Mountains, Gable Mountain and Umtanum Ridge, Yakima Ridge, and Rattlesnake Hills anticlines. The suprabasalt sediments are dominated by laterally extensive deposits assigned to the late Miocene to Pliocene Ringold Formation and the Pleistocene Hanford formation. The informally defined Plio-Pleistocene unit, early Palouse soil, and pre-Missoula gravels separate the Ringold Formation and Hanford formation locally.

I.1.3.4 Ringold Formation

The Ringold Formation consists of semi-indurated clay, silt, pedogenically altered sediment, fine to coarse grained sand, and gravel. The Ringold Formation at the Site is up to 180 m (600 ft) thick in the deepest part of the Cold Creek syncline south of the 200 West Area, but is largely absent in the northern and northeastern parts of the 200 East Area and adjacent areas to the north (Delaney et al. 1991, Reidel et al. 1992, and Cushing 1994).

Five sediment facies (or differentiation) associations, defined on the basis of lithology, stratification, and pedogenic (formation and development of soil) alteration, are recognized in the Ringold Formation (Delaney et al. 1991). These sediment facies include:

- Fluvial (produced by action of a stream) gravel deposited in wide-shifting river channels;
- Fluvial sand deposited in shallow channels incised into a muddy floodplain,
- Overbank-paleosol deposits that record deposition on a floodplain;
- Lacustrine (in-lake) deposits that record deposition in a lake; and
- Alluvial fan deposits that record deposition of basaltic detritus around the periphery of the Pasco Basin.

The distribution of facies associations within the Ringold Formation forms the basis for stratigraphic subdivision of the formation (Lindsey 1991). The lower half of the Ringold Formation contains five separate stratigraphic intervals dominated by fluvial gravels. These gravels, designated Units A, B, C, D, and E, are separated by intervals containing deposits typical of the overbank-paleosol and lacustrine facies associations (Delaney et al. 1991). The lowermost of the fine-grained sequences overlying Unit A is designated the lower mud sequence. The uppermost gravel unit, Unit E, grades upward into interbedded fluvial sand and overbank deposits that are in turn overlain by lacustrine-dominated strata.

The lower mud sequence (Figure I.1.3.3) consists of overbank and lacustrine deposits. The lower mud sequence is hydrologically substantive in that it is a potential confining layer that may offer some hydraulic separation between the saturated Ringold Formation above and the underlying Unit A gravels. The lower mud sequence is generally absent in the northern part of the 200 East Area and at the main lobe of B Pond (Trent 1992b). In the 200 West Area, the lower mud sequence is generally present throughout, except in the northeast corner (Trent 1992a). In the 200 West Area, the thickness of the lower mud sequence ranges from over 30 m (100 ft) in the south-central portion of the area to nonexistent in the northeast corner.

I.1.3.5 Post-Ringold and Pre-Hanford Units

Thin, laterally discontinuous alluvial deposits separate the Ringold Formation from the Hanford formation in various parts of the Hanford Site. These deposits are referred to informally as the Plio-Pleistocene unit, pre-Missoula gravels, and early Palouse soil (Figure I.1.3.3). The Plio-Pleistocene unit unconformably overlies the Ringold Formation in the western Cold Creek syncline in the vicinity of the 200 West Area. Depending on location, two types of materials may be present within the Plio-Pleistocene unit: 1) interfingering carbonate-cemented silt, locally referred to as the "caliche layer" (Trent 1992a), sand and gravel, carbonate-poor silt, and sand; and/or 2) basaltic detritus consisting of weathered and unweathered basaltic gravels deposited as locally derived slope wash, colluvium, and sidestream alluvium.

Pre-Missoula gravels are composed of quartzose to gneissic pebble-to-cobble gravel with a sand matrix. These gravels are up to 25 m (82 ft) thick, contain less basalt than underlying Ringold gravels and overlying Hanford deposits, have a distinctive white or bleached color, and sharply truncate underlying strata. The early Palouse soil consists of up to 20 m (66 ft) of silt and fine-grained sand. Deposits composing the early Palouse soil are massive, brownish-yellow, and compact.

I.1.3.6 Hanford Formation

The Hanford formation consists of pebble-to-boulder gravel, fine- to coarse-grained sand, and silt. These deposits are divided into three facies; gravel-dominated, sand-dominated, and silt-dominated (Figure I.1.3.3). These facies are referred to as coarse-grained deposits, plane laminated sand facies, and rhythmite facies, respectively (Reidel et al. 1992). The rhythmites also are referred to as the Touchet Beds or slack water deposits. The Hanford formation is thickest in the vicinity of the Central Plateau where it is up to 65 m (210 ft) thick. The Hanford formation was deposited by cataclysmic flood waters that drained out of a glacial lake named Missoula. Hanford Site deposits are absent on ridges more than approximately 385 m (1,260 ft) above sea level, the highest level of cataclysmic flooding in the Pasco Basin (Reidel et al. 1992).

Figure I.1.3.3 General Stratigraphy of the Suprabasalt Sediments of the Hanford Site

The sand-dominated facies was deposited adjacent to the main flood channelways and is found most commonly in the central Cold Creek syncline in the central to southern parts of the Central Plateau and in the vicinity of the Washington Public Power Supply System facilities. The silt-dominated facies was deposited under slack water conditions in back-flooded areas and is found throughout the central, southern, and western Cold Creek syncline within and south of the Central Plateau.

I.1.3.7 Holocene Surficial Deposits

Holocene surficial deposits consist of silt, sand, and gravel that form a thin (less than 10 m [30 ft]) veneer across much of the Hanford Site. These sediments were deposited by a mix of eolian (wind) and alluvial processes.

I.1.4 MINERAL RESOURCES

The geology of the potential Vernita Quarry and McGee Ranch borrow sites contains successions of basalts flows and suprabasalt sediments similar to those found on the Central Plateau and the areas near these sites along the Columbia River. The Vernita Quarry site is located in the Umatilla flow of the Saddle Mountain basalt. The Umatilla Flow at this location is composed of a single collonade characterized by columns 0.9 to 1.2 m (3.0 to 4.0 ft) wide. A bench approximately 12 to 15 m (40 to 50 ft) thick exists at the current quarry site and extends eastward as part of a series of benches that correspond to erode basalt flows along the valley of the Columbia River. The Pomona flow overlies the Umatilla flow and crops out approximately 300 m (1,000 ft) east of the existing quarry. The Pomona flow locally comprises a single colonnade with columns generally less than 0.6 m (2.0 ft) wide (Duranceau 1995).

At the potential McGee Ranch borrow site, a geological evaluation revealed a layer of fine-grained sediments immediately below the surface that range in thickness from 0.5 m to 10.0 m

(1.5 ft to 33 ft). A layer of silty, sandy gravel was identified directly beneath the surficial layer of fine-grained sediments. Hanford formation sediments overlay the Plio-Pleistocene unit and range in thickness from 0.15 to 12 m (0.5 to 40 ft). The ground surface at McGee Ranch is covered with pebbles, some cobble gravels and occasional boulders (DOE 1994h).

Currently no mineral resources other than crushed rock, sand, and gravel are produced from the Pasco Basin. Deep, natural gas production from anticlines in the basalt has been tested by oil exploration companies without commercial success. There are no current indications of any commercial mineral resource potential at any of the TWRS sites.

I.1.5 GEOLOGIC HAZARDS

Geologic processes that alter topography are landslides, floods, and volcanic activity. Each of these processes are briefly discussed in the following text as they relate to proposed TWRS activities.

I.1.5.1 Landslides

Landslides in the Ringold Formation sediments are common in areas where these sediments have been oversteepened by erosion, such as the White Bluffs area along the Columbia River. The likelihood of such oversteepening in the TWRS site areas is extremely low because of flat topography, a deep water table, and the absence of any actively eroding streams.

I.1.5.2 Floods

The nearest potential flooding source to the TWRS sites is Cold Creek. Studies of the probable maximum flood show that its effect is limited to the southwestern corner of the 200 West Area only (Cushing 1994). Because of the distance from the river, the probable maximum flood on the Columbia River would not impact the 200 Areas or any of the potential borrow sites. Failure of the upstream dams, either because of natural causes or sabotage, would not likely impact the 200 Areas or the potential borrow sites (Cushing 1994).

I.1.5.3 Volcanic Activity

Two types of volcanic activity have impacted the Pasco Basin in the past: basaltic flood volcanism and cascade-style diacitic volcanism to the west. The basaltic volcanism has been latent for the past eight million years and appears unlikely to resume because of changes in the plate tectonic regime of the region. The only source of volcanic activity that could impact the TWRS sites would be volcanism in the Cascade Mountain Range, more than 100 km (60 mi) west of the Hanford Site. The eruption of Mount St. Helens in 1980 is an example of such a volcanic event. This eruption caused considerable ashfall at the Hanford Site.

I.1.6 SEISMICITY

Seismicity at the Hanford Site is dominated by the position of the Site within the back-arc terrain of the Cascadia Subduction Zone formed where the Juan de Fuca Plate slides underneath the North American Plate (DOE 1995i). The back arc terrain of Washington occurs east of the Cascade Mountains and is underlain primarily by Jurassic to early Miocene metamorphic and volcanic rocks, which represent the accreted terrains of past collisions and continental deposits eroded from them (Reidel et al. 1989). Overlying a portion of this terrain is the Columbia Basalt Plateau, a region of thick tholeiitic basalt lava flows. The Hanford Site and proposed TWRS project sites lie within a subprovince of this basalt province known as the Yakima Fold Belt (RHO 1979).

The Yakima Fold Belt is characterized by narrow, linear anticlinal ridges of basalt and broad synclinal basins with an east to east southeast orientation. The folds have wavelengths of between 5 and 32 km (3 and 20 mi), amplitudes of less than 1 km (0.6 mi), and are commonly steeper on the northern limb. The faults in the subprovince appear to be associated with the folding and are found on the flanks of the folds. The folds extend eastward up to 113 km (70 mi) from the Cascade Range Province and were growing during the eruption and emplacement of the basalt and probably continue to grow at the present time (DOE 1988). In general, the structures do not impact the sediments that overlie the basalt.

Sources of seismic activity (earthquakes) at the Hanford Site include shallow structures in the Yakima Fold Belt or Columbia River Basalts. The orientation of the structural fabric of the Yakima Fold Belt suggests an origin by north-south compressional forces that operated from the middle Miocene age to the present. Compression during the extrusion of the lavas resulted in the folds propagating upwards through succeeding flows, folding the latest flow, and faulting the underlying flows (Reidel et al. 1989). The Hooper and Convey Model (Reidel et al. 1989) suggests that the compressive stress is horizontal and transmits deformation in a brittle manner only in the Columbia River Basalt Group (WHC 1993). It is believed that the underlying pre-basalt rocks deform in a ductile fashion and thus do not generate seismic activity. One of the most active areas of shallow earthquake activity is along the Saddle Mountain anticline, north of the Hanford Site (RHO 1979). Seismic activity within deep basement structures does not adequately explain the pattern of seismicity recorded in the region. The most recent seismic hazard analysis of the Hanford Site assumes that seismic activity occurs more or less randomly in the crust (WHC 1993). The source of seismic activity in the region that could potentially impact the Hanford Site is the Cascadia Subduction Zone, which lies off the coast of the Pacific Northwest. Two separate sources of seismic activity exist within this zone: an intraplate source where seismic events occur within the subducted Juan de Fuca oceanic plate, and an interplate source where seismic events occur at the interface of the Juan de Fuca and the North American plates. Of the two, the interplate source has the highest probability of generating earthquakes of a magnitude capable of causing ground motion at the TWRS sites that could impact the proposed facilities (WHC 1993).

I.1.6.1 Earthquake History

The Hanford Site lies in an area of relatively low seismic activity (Figures I.1.6.1. and I.1.6.2). Between 1870 and 1980 only five earthquakes occurred in the Columbia Plateau region that had Modified Mercalli Intensities (MMI) of VI or greater. All these events occurred prior to 1937. The largest event was the July 16, 1936 Milton-Freewater, Oregon earthquake (MMI=VII; surface wave magnitude = 5.8) (DOE 1988). The location of this earthquake and its association with known geologic structures are uncertain (DOE 1988).

Other earthquakes with a Richter magnitude of 5.0 or larger have occurred near Lake Chelan, Washington to the northwest, along the boundary of the Columbia Plateau and the Cascade Mountain range, west and north of the Hanford Site, and east of the Hanford Site in Washington State and northern Idaho. In addition, earthquake swarms of small magnitudes occur on and around the Hanford Site. An earthquake swarm is a series of earthquakes closely related in terms of time and space.

Seismicity with the Columbia Plateau can be segregated into three depth zones: 0 to 4 km (0 to 2.5 mi); 4 to 8 km (2.5 to 5 mi); and deeper than 8 km (5 mi). Approximately 70 to 80 percent of the seismic activity occurs in the 0 to 4 km (0 to 2.5 mi) zone, and 90 percent of the activity occurs in the first two zones (0 to 8 km [0 to 5 mi]) (DOE 1988). Most of the earthquakes in the central Columbia plateau are north or northeast of the Columbia River. Most of the earthquakes in the shallowest zone occur as swarms, which are not associated with mapped faults.

Figure I.1.6.1 Historical Seismicity of the Columbia Plateau and Surrounding Areas

Figure I.1.6.2 Recent Seismicity of the Columbia Plateau and Surrounding Areas as Measured by Seismographs

I.1.6.2 Seismic Hazards

Three major structures of the Yakima Fold Belt are found within the Hanford Site: the Umtanum Ridge-Gable Mountain Structure, the Yakima Ridge Structure, and the Rattlesnake Hills Structure. Each is composed of an asymmetrical anticline over-steepened to the north and with associated faults along their flanks. Two types of faults associated with the folds have been identified. Thrust faults occur on the northern, over-steepened limbs of the folds. These folds are sympathetic to the folds with more or less the same strike as the fold axes. Cross faults with a north-northwest trend cut the linear folds into separate segments and show a right lateral strike-slip movement (Reidel et al. 1989). Existing known faults within the Hanford area include wrench (strike-slip) faults, as long as 3 km (2 mi) on Gable Mountain and the Rattlesnake-Wallula Alignment, which has been interpreted as a right-lateral strike-slip fault. The faults in Central Gable Mountain are considered capable faults by Nuclear Regulatory Commission (NRC) criteria in that they have slightly displaced the Hanford formation gravels, but their relatively short lengths give them low seismic potential. No seismicity associated with the Gable Mountain Fault has been observed. The Rattlesnake-Wallula Alignment is interpreted to be capable faults by the NRC (Supply System 1981).

Earthquake sources considered relevant for the purpose of seismic design of TWRS facilities are the Rattlesnake-Wallula Alignment, Gable Mountain, an earthquake anywhere in the tectonic province, and the swarm area. For the Rattlesnake-Wallula Alignment, which passes along the southwest boundary of the Hanford Site, a maximum Richter magnitude of 6.5 has been estimated. For Gable Mountain, an east-west structure that passes through the northern portion of the Hanford Site, a maximum Richter magnitude of 5.0 has been estimated. An earthquake for the tectonic province was developed from the Milton-Freewater earthquake of Richter magnitude 5.75. A Richter magnitude 4.0 event is considered a maximum swarm earthquake for analyzing TWRS alternatives, based on the maximum swarm earthquake in 1973 (Cushing 1994). The Hanford Site current design basis for new facilities is for facilities to withstand a 0.2 gravity earthquake (Richter Magnitude of approximately 6.4) with a recurrence frequency of 2.0E-04.

I.1.7 SOIL

The surface and near-surface soils in the 200 Areas are not generally well developed and consist of a number of soil types: Rupert sand, Burbank loamy sand, and Ephrata sandy loam. Hezel sand is also present on the western boundary of the 200 West Area. Rupert sand consists of coarse sand and is also known as Quincy sand. Rupert sand covers the majority of the 200 West Area and approximately one-half of the 200 East Area. Burbank sand is coarse-textured sand that covers approximately the northeastern one-third of the 200 West Area, a relatively small portion of the 200 East

Area, and the majority of the area between the 200 West and 200 East Areas, where the potential Pit 30 borrow site (sand and gravel source) is located. Ephrata soil is medium-textured soil and covers the northern portion of the 200 East Area. Hezel sand is similar to Rupert sand and covers a portion of the area on, and immediately west of, the boundary of the 200 West Area. The predominant soil types in the general vicinity of the potential Vernita Quarry and McGee Ranch borrow sites are the Rupert sand and Burbank loamy sand.

I.1.7.1 Soil Contamination

Soil monitoring is conducted to detect the potential migration and deposition of radionuclides because of resuspension from other radioactive contaminated areas (wind-blown or water-borne) and waste intrusion by animals (PNL 1993a). The following contaminants have been consistently detectable in soil on the Hanford Site: cobalt-60 (Co-60), Sr-90, Cs-137, plutonium-239 (Pu-239), Pu-240, and uranium (U). Soil concentrations for these radionuclides were higher near and within Hanford Site facilities compared to offsite concentrations. In general, radionuclide concentrations near waste disposal sites are higher than concentrations further away.

Radiological surveys are conducted on Site areas that are known or suspected to contain surface or subsurface contamination. Areas that exceed specified levels are posted as radiologically controlled areas. A total of over 2,500 hectares (ha) (6,200 acres [ac]) of surface area and 1,030 ha (2,530 ac) of subsurface area were posted at the end of 1994. Ninety percent of the posted surface contamination area and 81 percent of the posted subsurface contamination area are in and near the 200 Areas. The net change in Sitewide surface contaminated areas reduced 44 ha (110 ac) from 1994 to 1995, which includes surface contamination areas, which includes a reduction of 33 ha (82 ac) in the 200 Areas. There was a corresponding net increase in Sitewide posted subsurface contamination areas of 44 ha (110 ac) from 1994 to 1995 , which includes an increase of 33 ha (82 ac) in the 200 Areas (PNL 1995).

I.2.0 WATER RESOURCES

Baseline conditions for water resources and hydrology encompass surface water, vadose zone, and groundwater, each of which may be impacted by implementing proposed TWRS activities.

I.2.1 SURFACE HYDROLOGY, INCLUDING FLOODPLAINS

The following subsections describe surface water resources, including the occurrence and characteristics of surface water, floodplains, and runoff.

I.2.1.1 Occurrence and Characteristics of Surface Water

West Lake and two small spring-fed streams in the Fitzner Eberhardt Arid Lands Ecology (FEALE) Reserve are the only naturally occurring water bodies on the Hanford Site. West Lake is several hectares in size and is located approximately 8 km (5 mi) northeast of the 200 West Area and about 3 km (2 mi) north of the 200 East Area. It is situated in a topographically low-lying area and is sustained by groundwater inflow resulting from an intersection with the groundwater table. West Lake was considered to be an ephemeral lake before operations began at the Hanford Site, with water level fluctuations dependent on groundwater level fluctuations. However, because of recharge (primarily from B Ponds) that contains low-level waste processing and cooling water from B Plant, water levels in the lake have become more stable.

Rattlesnake Springs, located 10 km (6 mi) west of the 200 West Area, forms a small surface stream that flows for approximately 2.5 km (1.6 mi) before it disappears into the ground as a result of seepage and evapotranspiration. The stream's base flow is approximately 0.01 cubic meters per second (m^3/sec) (0.4 cubic feet per second [ft^3/sec]). Snively Springs is located to the west and at a higher elevation than Rattlesnake Springs. It flows to the west and off of the Hanford Site (Cushing 1994).

Two ephemeral creeks, Cold Creek and its tributary, Dry Creek, traverse the uplands of the Hanford Site south and southwest of the 200 Areas. These creeks drain southeasterly toward the horn of the Yakima River, located south of the Hanford Site. Surface runoff from the uplands in and west of the Site is minor. These ephemeral creeks are not sustained by groundwater baseflow during any part of the year because depth to groundwater is over 46 m (150 ft) near the intersection of these creeks. The Columbia River is 16 to 24 km (10 to 15 mi) downgradient from the nearest TWRS site toward the east and approximately 11 km (7 mi) toward the north. The river forms the eastern boundary of the Hanford Site and comprises the base-level and receiving water for groundwater and surface water in the region.

I.2.1.2 Floodplains and Runoff

There are no floodplains in the 200 Areas. The potential Vernita Quarry and McGee Ranch borrow sites are also not within areas of high flood risk. Although floods in Cold Creek and Dry Creek have occurred historically, there have not been any observed flood events or evidence of flooding in these creeks that has reached the 200 Areas before infiltrating into permeable sediments.

Natural runoff generated onsite or from offsite upgradient sources is not known to occur in the 200 Areas. Measurable runoff occurs during brief periods in two locations, Cold Creek Valley and Dry Creek Valley, which are west and southwest of the 200 West Area (Newcomb et al. 1972). This surface runoff either infiltrates into the valley floor or evaporates. During periods of unusually rapid snowmelt or heavy rainfall, surface runoff extends beyond Rattlesnake Springs in the upper part of Dry Creek. However, this runoff quickly infiltrates into the alluvial sediments of Cold Creek Valley. The total amount of annual recharge to the unconfined aquifer from these areas is estimated to be 555,000 square meters (m^2) (5,970,000 square feet [ft^2]). This generally occurs east of the Hanford Site (Newcomb et al. 1972).

I.2.2 GROUNDWATER

Groundwater conditions in the 200 Areas are described in the following subsections in terms of the general hydrogeologic setting, vadose zone characteristics, aquifer characteristics, and groundwater flow. Groundwater conditions in the areas of the potential Vernita Quarry and McGee Ranch borrow sites are similar to those of the 200 Areas, although limited specific information is available. Groundwater quality and supply are discussed in Section I.2.3.

I.2.2.1 Hydrogeologic Setting

A thick vadose zone (approximately 70 m [200 ft] to over 90 m [300 ft] thick) as well as both confined and unconfined aquifers are present beneath the 200 Areas (DOE 1993a and b). The vadose zone is over 90 m (300 ft) thick in the vicinity of the TWRS site in the 200 East Area (DOE 1993a). The unconfined aquifer has not formally been named. This aquifer consists variably of the Ringold Formation (where present) and the lower portion of the Hanford formation. The confined aquifers are found primarily within the Columbia River Basalts. The confined aquifers are not a major focus of this EIS because they are separated from the TWRS facilities by the vadose zone, unconfined aquifer (the focus of the groundwater modeling effort), and confining layer(s) and thus are not likely to be impacted. The conceptual hydrogeologic column for the Hanford Site is illustrated in Figure I.2.2.1. Figure I.2.2.2 is a generalized cross section through the 200 Areas showing the major geologic units and the relative position of the water table. The water table is generally at or near the interface between the Hanford and Ringold formations, as illustrated in both Figures I.2.2.1 and I.2.2.2.

The occurrence and flow of groundwater in the unconfined aquifer must be described on a conceptual basis due to the difficulty of direct measurement. Five important concepts that describe flow in this aquifer are listed below:

1. The numerous strata within the Ringold Formation, described in the previous section on stratigraphy, result in a much lower vertical hydraulic conductivity compared to the horizontal hydraulic conductivity. This results in a strong preference for groundwater to move horizontally.
2. Groundwater movement occurs mostly in the upper portion of the Ringold Formation. That is, most groundwater movement occurs in the sands and gravel that predominate in the upper portion of the Ringold Formation (Unit E Gravels).
3. The overbank deposits and the lower mud sequence near the base of the Ringold Formation act as confining layers, hydraulically separating the overlying unconfined aquifer from the confined aquifer.
4. Recharge to the unconfined aquifer is primarily from artificial sources (e.g., B Pond), groundwater inflow from the Dry Creek and Cold Creek synclines, and recharge from the Columbia River along the western reach of the horn of the Colombia River near N Reactor.
5. Discharge from the unconfined aquifer is primarily to the Columbia River from the top of the horn south of the Columbia River to the 300 Areas, and in the vicinity of the B and C Reactors. Groundwater discharge also occurs to West Lake.

Natural recharge to the unconfined aquifer on the Hanford Site is extremely low and occurs primarily in the upland areas west of the Hanford Site. Artificial recharge from retention ponds and trenches contribute approximately 10 times more recharge than natural recharge. Seasonal water table fluctuations are not large because of the low natural recharge.

I.2.2.2 Vadose Zone Characteristics

The vadose zone extends from the ground surface to the top of the saturated sediments of the unconfined aquifer. Vadose zone characteristics determine the rate, extent, and direction of liquid flow downward from the surface. This zone variably includes the Hanford formation and locally includes the Ringold Formation Unit E Gravel. In the 200 West Area, the vadose zone is approximately 72 m (240 ft) thick (DOE 1993b). In the 200 East Area, the vadose zone is over 90 m (300 ft) thick, based on the 1991 depth to water level of the unconfined aquifer (DOE 1993a).

Figure I.2.2.1 Conceptual Hydrologic Column for the Hanford Site

Figure I.2.2.2 Generalized Cross Section of the Hanford Site

The following sections describe vadose zone characteristics (infiltration, perched water, and soil moisture) and vadose zone contamination .

I.2.2.2.1 Infiltration

The thick vadose zone, combined with the general aridity of the climate in the area, result in natural infiltration ranging from near zero (below detection) to approximately 11 centimeters per year (cm/yr) (4.3 inches [in.]/yr) (Gee et al. 1992). Some episodic recharge of groundwater may occur following periods of high precipitation, especially if combined with topographic depressions, highly permeable surface deposits such as gravel, and where the land is denuded of vegetation. Also, present conditions (bare ground and coarse sand and gravel surfaces) within the tank farms are conducive to higher infiltration than would be expected on undisturbed ground within the 200 Areas. For such conditions, infiltration near the upper range of 10 cm/yr (4.0 in./yr) would not be unreasonable. However, there are relatively recent changes that occurred after 1940 and would not necessarily have altered the flow within the full thickness of the vadose zone.

The total natural recharge in the 200 West Area is estimated to be approximately 1.3E+8 liters per year (L/yr) (3.4E+07 gallons [gal]/yr)(DOE 1993b). This is based on an average recharge rate of 0.1 cm/yr (0.04 in./yr) through fine-textured soil with deep-rooted vegetation. This value is approximately 10 times lower than recharge volumes from artificial sources.

The current principal sources of artificial recharge in the 200 West Area are four cribs and one ditch associated with the U Plant area, located in the eastern portion of the 200 West Area (DOE 1993b). There are also four septic tanks and drain fields that actively discharge water to the soil. The combined volume discharge from these drain fields is estimated to be 12,000 L/day (3,200 gal/day). The total wastewater discharged from these facilities from 1944 to 1992, including the U Plant cribs and ditches, is estimated to have been 1.7E+11 L (4.4E+09 gal). T Plant and S Plant operations also resulted in large volumes of wastewater discharged to the soil. Liquid is no longer discharged to the soil column from U, T, or S Plants.

Natural recharge in the 200 East Area is estimated to be approximately 2E+7 L (5E+06 gal) (DOE 1993a). This is based on a similar average natural recharge rate through fine-textured soil with deep-rooted vegetation, as noted previously for the 200 West Area. Artificial recharge in the 200 East Area is associated with approximately 140 ponds, trenches, cribs, and drains that were used to dispose of approximately 1E+12 L (3E+11 gal) of wastewater. The wastewater, except for limited discharges to the B Pond, is not directly discharged to the ground. The wastewater is treated to meet the State groundwater standards and piped to a common discharge location in the 200 Areas for discharge to the soil column. The remaining discharges to the ground at B Pond will be rerouted to the common discharge location in 1997. Currently, there are 11 active waste management units and 20 active drain fields. These waste management units are associated with B Plant and the Plutonium-Uranium Extraction (PUREX) Plant and are located east and northeast of the TWRS site (DOE 1993a). The primary recipients of the wastewater from three waste management units were the ponds and trenches associated with B Plant and PUREX Plant; the 216-A-25 and B-3 Ponds received approximately 7.0E+11 L (2.1E+11 gal) . Liquid is no longer discharged to the soil column from B Plant or the PUREX Plant.

Wastewater, such as the condensate removed from tank waste by the 242-A Evaporator, which is located in the eastern portion of the 200 East Area, is transferred by pipeline to the Effluent Treatment Facility, also located in the 200 East Area. The treated effluent from the Effluent Treatment Facility is then transferred by pipeline and discharged to the ground at the State-approved land disposal site located north of the 200 West Area. The treated wastewater meets all State groundwater discharge requirements except for tritium. The water is disposed of at this location further to the west so that the tritium contamination will decay to below drinking water standards in the groundwater before it reaches the Columbia River.

I.2.2.2.2 Perched Water

Perched water may occur within the vadose zone in the 200 West Area upon the caliche layer, approximately 55 m (180 ft) beneath the ground surface (DOE 1993b). Measured hydraulic conductivities of this unit range from 0.0009 to 0.09 m/day (0.003 to 0.3 ft/day). Caliche layers have not been encountered in the 200 East Area, and perched groundwater is not as likely to occur except in localized areas (Hoffman et al. 1992). Perched water has been reported in the vicinity of B Pond within the lower part of the Hanford formation.

I.2.2.2.3 Soil Moisture

In areas where artificial recharge is occurring from ponds and trenches, soil is expected to be close to saturation and would not likely be capable of holding substantial amounts of additional liquid. In addition, groundwater mounds have developed beneath these recharge areas. Where there is no artificial recharge, soil in the 200 Areas has a large moisture-holding capacity (DOE 1992a). The potential effect of recharge from Site waste water disposal activities is discussed in Volume Five, Appendix K, Section K.4.1.

I.2.2.2.4 Vadose Zone Contamination

Contaminants in the vadose zone in the 200 Areas are believed to be associated primarily with waste disposal practices that use engineered structures such as cribs, drains, septic tanks and associated drain fields, and reverse wells (wells that do not penetrate to the groundwater); percolation from ponds, ditches, and trenches such as B Pond and U Pond; and unplanned releases such as leaks from single-shell tanks (SSTs). The vadose zone is expected to be impacted by these past (and in some cases ongoing) waste management practices in the area immediately beneath the discharging facility and in an undetermined adjacent area (due to spreading as liquid percolates downward). Emerging data regarding vadose zone contamination from past SST leaks are provided in Volume Four, Appendix F, and Volume Five, Appendix K. Most Hanford Site environmental investigations have focused on the potential impacts of contaminants to the groundwater, not the vadose zone. Vadose zone investigations have often relied on geophysical gamma logs that are semi-quantitative. The types of contaminants potentially present in the vadose zone near planned and unplanned release sites can be inferred by contaminants detected in the underlying groundwater, contaminants that are reported in waste disposal inventories, or from the Track Radioactive Component (TRAC) inventory system used for SSTs that may be leaking. Table I.2.2.1 lists these contaminants, which include both radioactive materials (transuranic isotopes, U, and fission products) and nonradioactive materials (metals, volatile organics, semivolatile organics, and inorganics).

1.2.2.3 Aquifer Characteristics

Groundwater of the unconfined aquifer is found throughout the Hanford Site in the suprabasalt sediments and locally includes the Rattlesnake Ridge Interbed in the area north of the 200 East area, where erosion has removed a portion of the basalt sequence (Trent 1992b). The relationship between the various stratigraphic units and the hydrogeologic units is shown in Figure I.2.2.1.

Table I.2.2.1 Isotopes, Metals, and Organic Chemicals of Potential Concern at the 200 Areas

I.2.2.3.1 200 West Area

In the 200 West Area, the water table begins approximately 70 m (230 ft) beneath the surface. The saturated section, considered to be the unconfined aquifer, is composed of Ringold Formation Units A, B, C, D, and E gravels and is approximately 110 m (350 ft) thick above the Elephant Mountain member of the basalt. Hydraulic conductivities measured in the 200 West Area in the Ringold Unit E aquifer range from approximately 0.02 to 60 m/day (0.06 to 200 ft/day). Hydraulic conductivities range from 0.5 to 1.2 m/day (1.6 to 4.0 ft/day) in the semiconfined to confined Ringold Unit A Gravels (DOE 1993b). A discontinuous layer of silt and sand cemented by calcium-carbonate (caliche Plio-Pleistocene Unit), with a thickness up to 9 m (30 ft), occurs locally nearly 55 m (180 ft) in depth in the 200 West Area. This unit is believed to be responsible for perched water conditions in the vicinity of the TWRS sites in the 200

West Area.

I.2.2.3.2 200 East Area

Depth to groundwater in the 200 East Area ranges from 97 m (320 ft) in the southeast to 3 6 m (120 ft) in the vicinity of the 216-B-3C Pond (B Pond mound) located approximately 5 km (3 mi) east of the TWRS sites (DOE 1993a). The unconfined aquifer occurs within the Hanford and Ringold Formations. Groundwater near the TWRS sites occurs under unconfined conditions within the Ringold formation, approximately 96 m (315 ft) deep. The saturated (groundwater) section is approximately 34 m (110 ft) thick. Erosional windows occur in the basalt several kilometers north of the 200 East Area that allow some interconnection between the regionally confined Rattlesnake Ridge Interbed of the Ellensburg Formation in the basalt and the unconfined aquifer of the Hanford and Ringold Formations. Hydraulic conductivities of the unconfined aquifer near the TWRS sites in the 200 East Area range from 150 to 300 m/day (500 to 1,000 ft/day) (DOE 1993a).

I.2.2.4 Groundwater Flow

This section describes the physical characteristics of groundwater flow in the 200 Areas.

I.2.2.4.1 200 West Area

Figure I.2.2.3 is a contour map that shows the groundwater elevations for the Hanford Site. Groundwater generally flows from west to east, with some localized exceptions. In the northwest corner of the 200 West Area, groundwater flow is to the north. Also, it appears that flow from the 200 West Area may bifurcate east of the Gable Butte subcrop, with a lesser flow component north toward the gap between Gable Butte and Gable Mountain and the remaining flow east toward the Columbia River (Kasza 1994).

These groundwater movement patterns are also indicated by the 1994 distribution of tritium and nitrate in the unconfined aquifer, as shown on Figures I.2.2.4 and I.2.2.5, respectively. A north or northwest groundwater flow direction may also be indicated by the nitrate distribution in the area north and west of the 200 West Area. Because of the contrast in hydraulic conductivity, most basalt subcrops and outcrops appear as impermeable compared to groundwater flow in the transmissive Hanford and Ringold Formations.

Figure I.2.2.3 Groundwater Elevation Map of the Hanford Site

Figure I.2.2.4 Distribution of Tritium in the Unconfined Aquifer, 1994

Figure I.2.2.5 Distribution of Nitrate in the Unconfined Aquifer, 1994

The tank farms in the 200 West Area are located above a groundwater mound caused by artificial recharge from the U Plant area, especially the 216-U-10 Pond. Groundwater elevations have declined greatly since the 216-U-10 Pond was decommissioned in the fall of 1984. Large declines in groundwater elevations have been recorded in seven wells in the U Plant area since 1984. Hydrographs of two wells (299-W19-1 and 299-W19-10) west of the tank farms indicate that groundwater elevations have declined approximately 5 m (15 ft) since the 216-U-10 Pond was decommissioned. The mound seems to have shifted slightly as it continues to dissipate beneath 216-U-10 Pond toward the northeast beneath the 216-U-14 Ditch and 216-Z-20 Crib (DOE 1993b).

I.2.2.4.2 200 East Area

Groundwater flow in much of the 200 East Area is characterized by relatively low hydraulic gradients, ranging from 0.01 to 0.02 m/day (0.3 to 0.6 ft/day) (Kasza 1994). As shown in Figure I.2.2.3, water table elevations in the uppermost aquifer generally decrease from the margins of the Yakima Ridge in the west to the Columbia River in the east. There is a strong relationship between the water table as shown in Figure I.2.2.3 and the distribution of tritium in the uppermost aquifer as shown in Figure I.2.2.4. Both figures indicate that groundwater flow in the vicinity of the TWRS sites in the 200 East Area is toward the southeast.

I-129 is an unretarded contaminant (i.e., it moves with groundwater at the average groundwater velocity), as are nitrate and tritium. The distribution of i-129 in the unconfined aquifer (Figure I.2.2.6) also shows a southeasterly groundwater flow direction. The i-129 plume is much smaller than the plumes associated with nitrate and tritium, probably because i-129 sources are not as ubiquitous in the unconfined aquifer.

The mound resulting from discharge from the 216-B-3 Pond is a notable perturbation to the easterly flow direction. B Pond is approximately 5 km (3 mi) east of the TWRS sites. Near the western portion of the mound, the groundwater gradient has been reversed in a west direction. The magnitude of this gradient direction reversal is currently diminishing as the mound decays. The groundwater gradient in the southeastern portion of the 200 East Area is expected to resume a more easterly trend as the decay continues (Kasza 1994).

I.2.2.4.3 Vertical Gradients

Vertical hydraulic gradients in the unconfined aquifer are estimated from water measurements in wells that are near to each other (sometimes referred to as well pairs) and have their sensing zones (screened intervals) completed at different elevations within the unconfined aquifer. In both the 200 East and 200 West Areas, downward hydraulic gradients have been observed (Trent 1992, and b). In general, these downward hydraulic gradients are associated with the moundings that have been created from infiltration of water discharged to the U Pond and B Pond. Away from these mounds, the vertical gradients are smaller. For instance, near the Grout Treatment Facility in the 200 East Area, which is located along the central portion of the eastern part of the 200 East Area, the vertical head differences between nearby well pairs are so slight that they are indistinguishable from measurement errors (Trent 1992b). For information on the impact of the mounds on future groundwater flow see Appendix F, Section F.2.4.1.2.

Figure I.2.2.6 Distribution of Iodine-129 in the Unconfined Aquifer, 1994

I.2.2.4.4 Aquifer Communication

Aquifer communication is a process in which groundwater from distinct hydrogeological systems intermingle and mix. Of importance to the EIS is the degree of aquifer communication that exists between the unconfined aquifer and the underlying confined aquifer (Rattlesnake Ridge aquifer [Trent 1992b]). Several methods have been used to estimate the degree of aquifer communication at the Hanford Site including: analysis of joint and fracture systems in the basalt and presence of erosional windows, hydraulic head comparisons between aquifers, analysis and comparison of contaminant concentrations in adjacent aquifers, stable isotope analysis, and analysis of contaminant concentrations in adjacent aquifers. Interconnection between the unconfined and lower confined aquifer is possible across the Central Plateau; however, except for the area near the erosional windows, which occur in the basalt several kilometers north of the 200 East Area and B Pond vicinity, there is no indication of aquifer interconnection. In the vicinity of B Pond, groundwater mounding from B Pond discharges has resulted in a downward hydraulic gradient. Several kilometers north of the 200 East Area there is an absence of confining layer(s) associated with an erosional window that has resulted in enhanced interconnection of the aquifers in this area.

I.2.3 WATER QUALITY AND SUPPLY

Water for the Hanford Site is supplied by the Columbia River via distribution systems located at the 100-B, 100-D, 200, and 300 Areas, and at the Washington Public Power Supply System reactor. Wells supply water to the 400 Area and facilities at several remote locations. The city of Richland supplies water to the 700, 1100, and 3000 Areas.

Richland, Pasco, and Kennewick draw water from the Columbia River and operate their own water supply and treatment systems. Richland derives approximately 67 percent of its water from the Columbia River, 15 to 20 percent from a well field in North Richland, and the remaining 13 to 18 percent from groundwater wells (Cushing 1995). Richlands total water use in 1994 was 2.6E+10 L (6.9E+09 gal).

Pasco also obtains its water from the Columbia River and in 1994 consumed an estimated 8.6E+9 L (2.3E+09 gal) of water (Cushing 1995). The city of Kennewick's water supply is derived from the Columbia River and two wells. The wells serve as the sole source of water between November and March. The total maximum water supply for

Kennewick is approximately 2.8E+10 L (7.3E+09 gal); the wells can supply approximately 62 percent of that total. Kennewick's total water use in 1994 was 1.5E+10 L (3.9E+09gal) (Cushing 1995).

I.2.3.1 Surface Water

Surface waters considered for this EIS are onsite ponds, riverbank springs and seeps at the Columbia River, and the waters of the Columbia River. Water quality in ephemeral creeks is not known to be impacted by Hanford Site activities.

I.2.3.1.1 Columbia River

River water samples are routinely collected at the sample locations shown on Figure I.2.3.1. Additionally, river water samples have been collected at cross sections established at the Vernita Bridge upstream of the Hanford Site, and at the Richland City Pumphouse, downstream of the Hanford Site.

Radionuclides consistently detected in Columbia River water levels in 1995 were tritium, Sr-90, I-129, U-234, U-238, Pu-239, and Pu-240 (PNL 1996). Strontium-90 and tritium may come from worldwide fallout, as well as from releases of Hanford Site effluent. Tritium and U also occur naturally in the environment. Radionuclide concentrations at Priest Rapids Dam (upstream of the Site) generally were lower than those at the Richland Pumphouse (downstream from the Site), and were similar to levels observed in recent years.

All radiological contaminant concentrations measured in 1995 were less than the U.S. Department of Energy (DOE) Derived Concentration Guides and Washington State surface water quality standards (PNL 1996). Washington State classifies the Hanford Reach of the Columbia River as a Class A (Excellent) area. Class A waters are to be suitable for essentially all uses (e.g., raw drinking water, recreation, and wildlife habitat). Both State and Federal drinking water standards apply to the Columbia River and currently are being met (Neitzel 1996).

I.2.3.1.2 Ponds

Three ponds on the Hanford Site are routinely sampled: West Lake (located north of the 200 East Area), B Pond (located east of the 200 East Area), and the Fast Flux Test Facility Pond (located southeast of the 200 Areas) (PNL 1993a). Sampling data indicated that the ponds are impacted by Hanford Site activities, although the ponds are not used for human consumption. With the exception of U-234 and U-235 in the October 1995 sample of West Lake, all radionuclide concentrations were less than the DOE Derived Concentration Guides (PNL 1996) . Average annual total beta concentrations exceeded the ambient surface water quality criteria in West Lake. The U.S. Environmental Protection Agency (EPA) proposed Hanford Site-specific drinking water standards for U also was exceeded in West Lake. All other radionuclide concentrations were less than the applicable surface water quality criteria (PNL 1996) . West Lake surface water quality reflects the quality of the groundwater that feeds the lake (PNL 1993a).

Riverbank Springs and Seeps

Riverbank spring discharges have been documented along the Hanford Reach of the Columbia River since before the startup of Hanford Site operations. They have been observed to be of relatively small volume and to occur intermittently (PNL 1993a). Several springs in the 100 Areas, as well as the Old Hanford Townsite Springs and the 300 Area Springs, are routinely sampled. Water flows from these springs are a mechanism by which groundwater contaminated by past Site activities enter the river. All radiological contaminants measured in 1995 were less than the applicable DOE Derived Concentration Guides. However, Sr-90 in the 100-H Area and tritium in the 100- B Area and along the Old Hanford Townsite exceeded Federal and Washington State drinking water standards (PNL 1996) . Total U exceeded the proposed EPA Hanford Site-specific drinking water standards (PNL 199 6). The 1995 nonradiological contaminant concentrations were below Washington State ambient surface water toxicity standards with the exception of copper and zinc in the 100-K Area spring. The chronic toxicity level of cadmium and the EPA standard for trichlorethylene also were exceeded in the 100-K Area Spring (PNL 1996).

Figure I.2.3.1 Water and Sediment Sampling Locations, 1992

I.2.3.2 Groundwater

I.2.3.2.1 Supply

Groundwater is not used in the 200 Areas except for emergency purposes. Three wells for emergency cooling water are located near B Plant in the 200 East Area. Water for drinking, most emergency uses, and facilities processes is obtained from the Columbia River. There are no water supply wells downgradient of the 200 Areas. Water supply wells on the Hanford Site are located at the Yakima Barricade, 6 km (4 mi) west of the 200 West Area; in the 400 Area, 16 km (10 mi) southeast of the 200 Areas; and at the Hanford Safety Patrol Training Academy, 25 km (16 mi) southeast of the 200 Areas.

I.2.3.2.2 Water Quality

Contamination by both radionuclide and nonradionuclide contaminants has been identified in the groundwater beneath the Hanford Site. Liquid effluents have been discharged to various ponds, cribs, and other Hanford Site waste management structures. Adsorption into soil particles, chemical precipitation, and ion exchange attenuate or delay the movement of some radionuclides and nonradionuclide contaminants in the effluent as they percolate downward through the vadose zone (PNL 1993a).

Constituents such as Sr-90, Cs-137, Pu-239, and Pu-240 are attenuated to varying degrees but eventually enter the groundwater. Compounds such as nitrate and radionuclides such as tritium, technetium-99 (Tc-99), and I-129 are not readily attenuated in the soil and reach the groundwater sooner than those that are. These ions then travel downgradient at the same rate as the natural groundwater (PNL 1993a). Figure I.2.2.4 shows the distribution of tritium in the unconfined groundwater. Two other major contaminant plumes include nitrates (Figure I.2.2.5) and I-129 (Figure I.2.2.6).

Groundwater beneath the 200 Areas and in plumes leading from the 200 Areas toward the Columbia River is contaminated with hazardous chemicals and radionuclides at levels that exceed Federal drinking water standards and State groundwater criteria. Hazardous chemical contaminants present at levels exceeding drinking water standards and State groundwater criteria include nitrates, cyanide, fluoride, chromium, chloroform, carbon tetrachloride, trichloroethylene, and techrachloroethylene. Radiological contaminants include I-129, tritium, Cs-137, Pu-239, Pu-240, and Sr-90. Generally, the groundwater contamination beneath the 200 Areas substantially exceeds drinking water standards and State groundwater criteria. For example, I-129 is present at levels that exceed standards by up to 20 times. While other groundwater plumes from the 200 Areas tend to have lower levels of contaminants than the I-129 levels, many contaminants still exceed drinking water standards and State groundwater criteria. Groundwater use is controlled at the Hanford Site to prevent use of contaminated groundwater.

I.2.3.2.3 200 East Area

Unconfined groundwater beneath the 200 East Area contains 13 different contaminants that have been mapped as plumes: arsenic, chromium, cyanide, nitrate, gross alpha, gross beta, tritium, Co-60, Sr-90, Tc-99, I-129, Cs-137, Pu-239, and Pu-240 (DOE 1993a).

I.2.3.2.4 200 West Area

Beneath the 200 West Area, 13 overlapping contaminant plumes are located within the unconfined gravels of Ringold Unit E: Tc-99, U, nitrate, carbon tetrachloride, chloroform, trichloroethylene, I-129, gross alpha, gross beta, tritium, arsenic, chromium, and fluoride (DOE 1993b). The tank farms are within the boundaries of most of these plumes. Plumes of Tc-99, U, I-129, gross alpha, and gross beta are associated with the U Plant area.

I.3.0 METEOROLOGY AND AIR QUALITY

The following subsections discuss Hanford Site climatology and air quality. The meteorological section summarizes measurements of wind, temperature and humidity, precipitation, fog and visibility, severe weather, and atmospheric dispersion. The air quality section includes information on air quality standards, emissions sources, and air quality monitoring.

I.3.1 METEOROLOGY

The Cascade Mountains greatly influence the climate of the Hanford Site by their rain shadow effect. This range also serves as a source of cold air drainage, which has a considerable effect on the wind regime over the Site.

Climatological data has been collected at Hanford Meteorological Monitoring Network sites. The Hanford Meteorological Station (HMS), located between the 200 East and 200 West Areas, is the most completely instrumented station. The HMS data are considered representative for assessing proposed TWRS activities. The following meteorological discussion is largely based on the Hanford Climatological Summaries (Stone et al. 1972), as well as information compiled by Cushing (Cushing 1994).

I.3.1.1 Wind

Figure I.3.1.1 shows winds measured at the Meteorological Monitoring Network sites. Prevailing winds at the HMS are from the west-northwest and northwest in all months of the year. Monthly average wind speeds are lowest during December, averaging 10 km/hr (6 mi/hr), and highest during June, averaging approximately 15 km/hr (9 mi/hr). The most prevalent wind speed class,

6 to 11 km/hr (4 to 7 mi/hr), occurs 36 percent of the time. Wind speeds are less than 21 km/hr (13 mi/hr) 84 percent of the time, and greater than 29 km/hr (18 mi/hr) less than 5 percent of the time. Peak gusts occur from the south-southwest, southwest, and west-southwest during all months.

Figure I.3.1.1 Hanford Meteorological Monitoring Network Wind Roses for the Period from 1982 through 1993

I.3.1.2 Temperature and Humidity

From 1961 through 1990, the average monthly temperatures varied from -1 centigrade (C) (30.3 Fahrenheit [F]) in January to 24.6 C (76.2 F) in July with a yearly average of 11.8 C (53.2 F). On the average, 51 days during the year (April through September) had maximum temperatures greater than or equal to 32 C (90 F), and 12 days (May through September) had a maximum temperature greater than or equal to 37.8 C (100 F). Also, an average of 25 days during the year (October through February) experienced maximum temperatures less than 0 C (32 F). An average of 106 days per year (October through April) experienced minimum temperatures less than 0 C (32 F). An average of 4 days per winter season (November through February) experienced daily minimum temperatures less than -18 C (0 F) but approximately half of all winters were free of such days. The record maximum and minimum temperatures recorded during the period 1945 to 1991 were 45 C (113 F) in 1961 and -45 C (-23 F) in 1950.

The annual average relative humidity, based on data from the years 1950 through 1993, was 54.5 percent. Relative humidity was highest during the winter months, averaging 80.2 percent in December, and lowest during the summer, averaging 33.3 percent in July.

I.3.1.3 Precipitation

The average annual precipitation measured at the HMS is 17 cm (6.6 in.). The bulk of the precipitation (54 percent) occurs during November through February. As the wettest month, December receives an average of 2.5 cm (1 in.) of precipitation while July averages 0.5 cm (0.2 in.) and is the driest month. On the average, only 1 day per year experiences precipitation greater than 1.3 cm (0.5 in.), and 68 days per year have precipitation greater than 0.02 cm (0.01 in.) per year. An average of 125 days per year receive a trace amount or more of precipitation. The monthly total time during which precipitation occurs ranges from 12.4 percent in December to 1.5 percent in July. Winter monthly average snowfall ranges from 0.8 cm (0.3 in.) in March to 13.5 cm (5.3 in.) in January. Yearly snowfall has ranged from 0.8 cm (0.3 in.) to 140 cm (56 in.). Annual average snowfall is 38 cm (15 in.).

I.3.1.4 Fog and Visibility

Although fog (visibility less than or equal to 10 km [6 mi]), has been recorded during every month of the year at the HMS, nearly 90 percent of the occurrences are during the late fall and winter months. The months of April through September account for only about 1 percent of the occurrences. On average, 46 days per year experience fog and 24 days per year experience dense fog (visibility less than or equal to 0.4 km [0.25 mi]).

Other phenomena restricting visibility to 10 km (6 mi) or less include dust, blowing dust, and smoke (typically from wildfires, orchard smudging, and agricultural field burning). An average of 5 days per year have dust or blowing dust and only about 2 days per year have reduced visibility resulting from smoke. On an annual basis, 3.8 percent of the hourly observations recorded for the years 1960 through 1980 indicate restricted visibility because of all phenomena.

I.3.1.5 Severe Weather

Severe high winds are associated with thunderstorms. On average the Hanford Site may experience 10 thunderstorms per year, most frequently (80 percent) occurring May through August. However, thunderstorms have been observed to occur in every month of the year. Estimates of the extreme wind velocities, based on peak gusts observed from 1945 through 1980, are shown in Table I.3.1.1 (Stone et al. 1983).

Tornadoes are smaller and less frequent in the northwest portion of the United States than elsewhere in the country. There were no reports of violent tornadoes for the region surrounding the Hanford Site. The HMS climatological summary (Stone et al. 1983) and the National Severe Storms Forecast Center database list 22 separate tornado occurrences within 160 km (100 mi) of the Hanford Site from 1916 through August 1982. Two additional tornadoes have been reported since August 1982. The probability of a tornado striking at the Hanford Site has been estimated to be approximately one in 10,000 (NRC 1977).

Table I.3.1.1 Estimates of Extreme Winds at the Hanford Site

I.3.1.6 Atmospheric Dispersion

Atmospheric dispersion is a function of wind speed, duration and direction of wind, atmospheric stability, and mixing depth. Dispersion conditions are generally good if winds are moderate to strong, the atmosphere is of neutral or unstable stratification, and there is a deep mixing layer. Good dispersion conditions associated with neutral and unstable stratification exist about 57 percent of the time during the summer at the Hanford Site. Less favorable dispersion conditions may occur when the wind speed is light and the mixing layer is shallow. These conditions are most common during the winter when moderately to extremely stable stratification exists about 66 percent of the time. Less favorable conditions also occur periodically for surface and low-level releases in all seasons from sunset to 1 hour after sunrise as a result of ground-based temperature inversions and shallow mixing layers. Mixing layer thicknesses have been estimated at the HMS using remote sensors. The variations in the mixing layer are summarized in Table I.3.1.2.

The Hanford Site may experience occasional extended periods of poor dispersion conditions associated with stagnant air in stationary high-pressure systems that occur primarily during the winter months.

Table I.3.1.2 Percent Frequency of Mixing-Layer Thickness by Season and Time of Day

The probability of an inversion period (e.g., poor dispersion conditions) extending more than 12 hours varies from a low of about 10 percent in May and June to a high of about 64 percent in September and October (Stone et al. 1972).

I.3.2 AIR QUALITY

Federal and State ambient air quality standards have been set for a limited number of pollutants. Monitoring is conducted to measure levels of selected pollutants that can then be compared to the standards.

I.3.2.1 Air Quality Standards

National Ambient Air Quality Standards (NAAQS) have been established by EPA, as mandated in the 1970 Clean Air Act. Ambient air is the portion of the atmosphere, external to buildings, that is accessible to the general public. The NAAQS define levels of air quality that, with an adequate margin of safety, are protective of public health (primary standards) and welfare (secondary standards). NAAQS exist for the following six criteria pollutants; sulfur oxides (measured as sulfur dioxide), nitrogen dioxide, carbon monoxide, particulate matter (PM-10, measured as particles less than 10 micrometers [µm] aerodynamic diameter), lead, and ozone. The standards specify the maximum pollutant concentrations and frequencies of occurrence that are allowed for various averaging periods ranging from 1 hour to 1 year depending on the pollutant.

Washington State has largely adopted the current NAAQS. However, Washington State has established more stringent standards for sulfur dioxide and ozone and maintains an air quality standard for total suspended particulates and gaseous fluorides. Table I.3.2.1 summarizes the NAAQS and supplemental Washington State standards.

The Hanford Site also evaluates concentrations of selected pollutants for which national and State ambient air quality standards do not exist. For toxic organic compounds (e.g., toluene, benzene), comparisons are made to the Occupational Safety and Health Administration's maximum allowable concentrations (29 Code of Federal Regulations [CFR] 1910). Concentrations of polychlorinated biphyenyls are compared against the National Institute of Occupational Safety and Health limit of 1,000 micrograms per m^3 ($\mu g/m^3$) as a 10-hour time-weighted average.

Table I.3.2.1 Federal and Washington State Ambient Air Quality Standards

I.3.2.2 Emission Sources

Sources of airborne emissions at the Hanford Site include combustion equipment (e.g., steam boilers, electric generation plants), coal handling operations, chemical separation processes, storage tanks, waste handling, and waste disposal. These activities result in routine emissions of air pollutants, including radionuclides.

The Clean Air Act amendments of 1990 established a new national permitting system for major sources of air pollution, and other categories of sources, such as facilities with equipment subject to a National Emission Standard for Hazardous Air Pollutants (NESHAP). The Hanford Site is classified as a major source for one or more criteria pollutants, as well as for hazardous air pollutants. The Hanford Site is currently subject to the radionuclide NESHAP of 10 millirems (10 mrem) per year. DOE has applied for a Sitewide Air Operating Permit for the Hanford Site, which will cover all substantial emission sources for which the Site is considered a major source.

For areas in attainment of the NAAQS, the EPA has established the Prevention of Significant Deterioration (PSD) program to protect existing ambient air quality while at the same time allowing a margin for future growth. Under the PSD program, new stationary sources of air pollution may only impact air quality by set increments and they must install best available control technology emission controls. The Hanford Site obtained a PSD permit in 1980 requiring specific limits for oxides of nitrogen emitted from the PUREX Plant.

I.3.2.3 Air Quality Monitoring

Air quality data have been collected at onsite and offsite locations. The following discussion concentrates on recent monitoring activities conducted largely for the purpose of assessing air quality impacts from the Hanford Site. The information was taken from the Hanford Site Environmental Report (PNL 1995 and 1996) and from the Site NEPA Characterization Report (Cushing 1995 and Neitzel 1996).

I.3.2.3.1 Onsite Monitoring

Onsite air quality monitoring was conducted during 1990 for nitrogen oxides at three locations. The monitoring was discontinued after 1990 because the primary source ceased operation. The highest annual average concentration was less than 0.006 parts per million (ppm), well below the applicable Federal and Washington State annual ambient standard of 0.05 ppm.

Based on a review of chemicals of concern for surveillance at PCBs, the Site, three types of semi-volatile organic compounds were identified for monitoring: polycyclic aromatic hydrocarbons, and a phthalate ester plasticizer. Organochlorine pesticides also were analyzed. Four polycyclic aromatic hydrocarbons, 19 polychlorinated biphenyl congeners, and 16 organochlorine pesticides were found above detection limits. The measured concentrations of pesticides were orders of magnitude below the occupational maximum allowable concentration values. No phthalate esters were found above detection limits (PNL 1996).

Nine of a total 17 PCB samples collected during 1993 were below the detection limit of 29 µg/m^3. Eight PCB samples were above the detection limit, with values ranging from 0.25 to 3.9 µg/m^3, all well below the National Institute of Occupational Safety and Health occupational limit of 1,000 µg/m^3. Fourteen volatile organic compound samples were obtained in 1993. All samples analyzed for benzene, alkylbenzenes, halogenated alkanes, and alkenes were within allowable limits. Volatile organic compound data from 1994 were within a similar range of values and also were within allowable limits.

I.3.2.3.2 Offsite Monitoring

The only offsite monitoring in the vicinity of the Site in 1993 was conducted by Washington State Department of Ecology. PM-10 was monitored at Columbia Center in Kennewick. The State's 24-hour PM-10 standard was exceeded twice in 1993. The maximum reading was 1,166 µ/m^3, with the suspected cause being windblown dust. There was no exceedance of the annual primary standard of 50 µg/m^3(Cushing 1995).

Particulate concentrations can reach relatively high levels in eastern Washington State because of exceptional natural events (i.e., dust storms, volcanic eruptions, and large brush fires) that occur in the region. State ambient air quality standards have not distinguished rural fugitive dust from exceptional natural events when estimating the maximum background concentrations of particulates in the area east of the Cascade Mountain crest. No decision has been made to designate Benton County a nonattainment area pending studies to determine the source of high local PM-10 concentrations. It is suspected that the high readings are due to natural conditions (e.g., dust storms, brush fires) rather than man-made pollution.

I.3.2.3.3 Radiological Monitoring

Data were collected in 1995 through a system of 47 radiological monitoring stations located onsite, at the Site perimeter, in nearby communities (e.g., Richland, Kennewick, and Pasco), and in distant communities (Sunnyside and Yakima). Cesium-137, Pu-239, Pu-240, Sr-90, and U were consistently detected in air samples collected in the 200 Areas. Concentrations of these radionuclides were higher than concentrations measured offsite and were in the same range as measured in recent years . The levels measured at both onsite and offsite locations were much lower than the applicable standards (PNL 1996) .

I.4.0 BIOLOGICAL AND ECOLOGICAL RESOURCES

This section describes the ecological resources potentially impacted by the proposed action and alternatives. A brief description of the regional environment is followed by a discussion of the ecological resources of the Central Plateau and nearby areas, which are the location of all facilities under all alternatives addressed in this EIS. The material presented is based largely on reports by Cushing (Cushing 1994 and 1995), which summarize many other site studies, on the 1994 biological survey of the TWRS site in the 200 East Area (PNL 1994e), and on the Site Evaluation Report for Candidate Basalt Quarry Sites (Duranceau 1995).

The Hanford Site and adjacent region have been characterized as shrub-steppe (Daubenmire 1970). Shrub-steppe vegetation zones are dominated by a shrub overstory with an understory of grasses. The Hanford Site has not been farmed or grazed by livestock for more than 50 years, allowing it to serve as a refuge for a variety of plant and animal species (Gray-Rickard 1989). Approximately 665 km^2 (257 mi^2) of undeveloped land within the Hanford Site have been designated as ecological study areas or refuges. Washington State considers shrub-steppe a priority habitat because of its importance to wildlife species of concern. The National Biological Service has identified native shrub and grassland steppe in Washington State and Oregon as an endangered ecosystem.

I.4.1 BIODIVERSITY

Biodiversity has been defined as the diversity of ecosystems, species, and genes, and the variety and variability of life (CEQ 1993). Major components of biodiversity are plant and animal species, microorganisms, ecosystems, and ecological processes, and the interrelationships between and among these components. Biodiversity also is a qualitative measure of the richness and abundance of ecosystems and species in a given area (NPS 1994). Biodiversity also provides a moderating effect on wide fluctuations in environmental conditions.

Two major factors that contribute to biodiversity on the Hanford Site are 1) the Site is one of the largest relatively undisturbed tracts of native shrub-steppe left in Washington State; and 2) the Hanford Reach is the last free-flowing nontidal stretch of the Columbia River in the United States (Sackschewsky et al. 1992 and Cushing 1994). Other factors include topographic features such as Rattlesnake Mountain, Gable Butte, and Gable Mountain, a variety of soil textures ranging from sand to silty and sandy loam, and the lack of human use and development over much of the Hanford Site. Specialized terrestrial habitats contributing to the biodiversity of the Hanford Site include areas of shrub-steppe, basalt outcrops, scarps (cliffs), scree slopes (accumulations of material at the base of a hole or cliff), and sand dunes. Aquatic components of biodiversity are mainly associated with the Columbia River and include aquatic habitat, wetland and riparian areas, and riverain habitat along the Hanford Reach shoreline and islands in the Columbia River.

The biological diversity of the Hanford Site has been emphasized by the recent discovery of 21 new species (two plant and 19 insects) in a study by the Nature Conservancy of Washington (Nature Conservancy 1996) . These species may be dependent on the shrub-steppe environment and destruction, fragmentation, or other disturbance of this habitat could lead to the loss of these and other as yet unidentified species. None of these newly recorded species were found in potential TWRS areas (Brandt 1996).

Ecologically important plant and animal species on the Hanford Site include species of concern (Section I.4.6); commercial and recreational wildlife species such as salmon and steelhead, mule deer, and upland game birds; and plant species used as a source of food, medicine, fiber, and dye in the traditional lifestyles of Native People of the Columbia Basin (Section I.4.7) (Sackschewsky et al. 1992).

As stated previously, the Hanford Site has not been farmed or grazed for over 50 years and thus has served as a refuge for various plant and animal species. However, the invasion and spread of nonnative plant species into previously disturbed areas, such as abandoned farmland, represent a potential threat to biodiversity by displacing native species, simplifying plant communities, and fragmenting habitat. Introduced plant species account for approximately 21 percent of the vascular plants found on the Hanford Site and include species such as cheatgrass, Russian-thistle, and most of the tree species found onsite (Sackschewsky et al. 1992). Most of the Site's disturbed areas include abandoned farmland and areas burned by wildfire. These areas are dominated by pure stands of cheatgrass where the native shrub component has been modified severely or replaced altogether (Cushing 1994).

I.4.2 VEGETATION

The Hanford Site is a relatively undisturbed area of shrub-steppe, which is considered priority habitat by Washington State (WSDW 1993). Also, the National Biological Service has listed native shrub and grassland steppe in Washington and Oregon as an endangered ecosystem. Historically, the predominant plant in the area was big sagebrush (*Artemisia tridentata*) with an understory of perennial bunch grasses such as Sandbergs bluegrass (*Poa sandbergii*) and bluebunch wheatgrass (*Agropyron spicatum*). Following human settlement in the early 1800's, grazing and agriculture disrupted the native vegetation and opened the way for invader species such as tumbleweed or Russian-thistle (*Salosa kali*) and cheatgrass (*Bromus tectorum*). Establishing the Hanford Site as a nuclear facility in 1943 created a protected area of mostly undeveloped land with scattered, small industrial complexes. Consequently, the Hanford Site is one of a small number of remaining shrub-steppe tracts in Washington State that is relatively undisturbed.

The Central Plateau and the nearby areas of the potential McGee Ranch and Vernita Quarry borrow sites have been identified as predominantly shrub-steppe (Cushing 1994 and Duranceau 1995). This designation includes communities dominated by big sagebrush and bitterbrush (*Purshia tridentata*) with an understory of cheatgrass or Sandbergs bluegrass (Figure I.4.2.1). Over 100 plant species occur on the Central Plateau and vicinity. Common plant species include big sagebrush, rabbitbrush (*Chrysothamnus nauseous*), cheatgrass, and Sandbergs bluegrass(Table I.4.2.1). Much of the 200 Areas (e.g., the tank farms, the sites of several large processing facilities), have been disturbed by human activities. In these disturbed areas, introduced species, such as Russian-thistle and cheatgrass are common (Cushing 1994).

The TWRS sites in the 200 East Area and the immediate surrounding area are approximately 40 percent big sagebrush and rabbitbrush. Another 20 percent is dominated by Russian-thistle, with the remainder disturbed vegetation or bare gravel (PNL 1994e). The proposed Phased Implementation alternative site in the easternmost portion of the 200 East Area is comprised of approximately 65 percent shrub-steppe, with the remaining area disturbed by the construction in the 1980's of the unused Grout Treatment Facility (ASI 1995).

Figure I.4.2.1 TWRS Areas Vegetation Types (Simplified)

Table I.4.2.1 Common Vascular Plants Found on the Hanford Site

Other vegetation in the 200 Areas includes wetland species associated with man-made ditches and ponds and introduced perennial grass planted to revegetate disturbed areas. Wetland species such as cattail, reeds, and various trees, such as willow, cottonwood, and Russian-olive, are established around some of these ponds (Cushing 1992). However, several of the ponds have been decommissioned, which eliminated the supply of industrial water feeding the ponds. Without the water supply, the artificial wetland habitat was eliminated. None of the wetlands or ponds are near the TWRS sites.

Introduced perennial grass, such as Siberian-wheatgrass (*Agropyron sibericum*), has been used extensively in the 200 Areas to revegetate and stabilize waste burial grounds against wind and water erosion. Siberian-wheatgrass has proven to be drought tolerant and better adapted to sandy soil than other species used in the 200 Area's revegetation (Stegen 1993).

At the potential Vernita Quarry borrow site, the areas at the top of the basalt cliffs have very low shrub densities, primarily big sagebrush and rigid sagebrush. Grasses such as bluebunch wheatgrass and Sandbergs bluegrass are common. Areas between and below the basalt cliffs have shrub coverage of 30 to 40 percent, primarily big sagebrush with some spiny hopsage and prickly phlox (Duranceau 1995).

The potential McGee Ranch borrow site contains a wide variety of shrubs and flowering plants. Large portions of the site are covered with a dense stand of big sagebrush and spiny hopsage. This area has a Sandbergs bluegrass understory with very little cheatgrass or other alien weed species (Duranceau 1995). Approximately 25 percent of the site is abandoned farmland and is dominated by cheatgrass and Russian-thistle. The McGee Ranch area also is an important vegetation and wildlife corridor linking the Hanford Site and the Yakima Training Center, which are two largest shrub-steppe areas remaining in Washington State (Fitzner 1992). In 1996, the Washington State Department of Fish and Wildlife asked DOE to preserve the McGee Ranch area as a wildlife corridor (Baker 1996).

The Nature Conservancy of Washington recently discovered a new species of buckwheat in the Umtanum Ridge area, which is in the same general area of the Hanford Site as McGee Ranch and Vernita Quarry (Nature Conservancy 199 6).

I.4.3 WILDLIFE

Approximately 290 species of terrestrial vertebrates have been observed at the Hanford Site, including 41 species of mammals, 238 species of birds, three species of amphibians, and nine species of reptiles (Weiss-Mitchell 1992). Major terrestrial habitat types occurring on the Site include basalt outcrops, scarps and screes, riparian and riverain areas, shrub-steppe, sand dunes and blowouts, and abandoned fields (Downs et al. 1993).

I.4.3.1 Mammals

Common large mammal species include the mule deer and Rocky Mountain elk; predators such as coyotes, bobcats, and badger; and a variety of small mammals (Table I.4.3.1). Elk were not present when the Hanford Site was established in 1943 and did not appear onsite until 1972. The elk occur primarily on the FEALE Reserve, although they also may be found elsewhere on the Site, such as on the islands and along the Columbia River (PNL 1993a). Mule deer may occur almost anywhere on the Hanford Site, although concentrations are highest along the Columbia River between the Hanford townsite and the B Reactor area (Rickard et al. 1989). White-tailed deer are occasionally sighted along the Columbia River and at the Yakima River Delta near Richland (Fitzner-Gray 1991). Six species of bats also occur on the Hanford Site, primarily as fall or winter migrants, with some using abandoned buildings as roosting sites (Cushing 1992).

I.4.3.2 Birds

Bird species on the Site include a variety of raptors, songbirds, and species associated with riparian, riverain, and upland habitats. Approximately 240 species of birds, including migrants and accidental species, have been observed at the Hanford Site (Landeen et al. 1992). Of these, 36 are common species (Table I.4.3.2) and 40 occur as accidental species (Cushing 1994).

Common raptors that may occur onsite year-round are the northern harrier, red-tailed hawk, golden eagle (*Aquila chrysaetos*), prairie falcon (*Falco mexicanus*), American kestrel (*Falcosparverius*), barn owl (*Tyle albu*), great horned owl (*Bubo virginianus*), and long-eared owl (*Anio olus*) (Fitzner-Gray 1991). Raptors use a variety of habitats for nesting and foraging at the Hanford Site. Nest habitat include outcrops and cliffs, trees, marsh lands and fields, and utility towers. Depending on raptor size and species, prey may include small mammals, birds, reptiles such as snakes, and insects.

A variety of passerine (songbird) species is known to occur in the shrub-steppe vegetation type on the Hanford Site. These include the western meadowlark (*Sturnella neglecta)*, grasshopper sparrow (*Ammodramus savannarum*), horned lark (*Eremophila alpestris)*, and sage thrasher (*Oreoscoptes montanus*) (Downs et al. 1993). The western meadowlark and horned lark are the most abundant shrub-steppe passerine bird species that breed on the Hanford Site (Rickard-Poole 1989). The western meadowlark and horned lark nest on the ground in the open, while shrub-steppe species like the sage sparrow, sage thrasher, and loggerhead shrike require sagebrush or bitterbrush for nesting habitat.

Table I.4.3.1 List of Mammals Occurring on the Hanford Site

Table I.4.3.2 Common Birds Occurring on the Hanford Site

Common upland game bird species include the chukar partridge (*Alectoris chukar*), california quail (*Callipepla californicus*), and chinese ring-necked pheasant (*Phasianus colchicus*). Sage grouse (*Centrocercus urophasianus*) and gray partridge (*Perdix perdix*) are less common and rarely seen. Although once more common, sage grouse are now essentially absent from the Site, displaced after a major wildfire in 1984 (Brandt 1995). None of the upland birds are native to the area except the sage grouse.

I.4.3.3 Reptiles and Amphibians

Nine species of reptiles and three species of amphibians occur on the Hanford Site (Table I.4.3.3) (Fitzner-Gray 1991). The most abundant reptile is the side-blotched lizard (*Uta stansburiana*) (Cushing 1992). The short-horned lizard (*Phrynosoma douglassii*) and northern sagebrush lizard (*Sceloporous graciosus*) are also common in mature sagebrush habitats with sandy soil. Common snakes include the gopher snake (*Pituophis melanoleucus*), yellow-bellied racer (*Coluber constrictor*), and pacific rattlesnake (*Crotalus viridis*). Less common are striped whipsnakes (*Masticophis taeniatus*) and desert night snakes (*Hyspiglena torquata*). Amphibians on the Hanford Site are associated with riparian habitats located along permanent water bodies or the Columbia River (Fitzner-Gray 1991). Included are the Great Basin spadefoot (*Spea intermontana*), Woodhouses toad (*Bufo woodhouseii*), and the Pacific tree frog (*Hyla regilla*).

Table I.4.3.3 Amphibians and Reptiles Occurring on the Hanford Site

I.4.3.4 Insects

The Nature Conservancy of Washington, in an ongoing multi-year inventory project, has identified approximately 1,2 00 species of insects on the Hanford Site. This includes the discovery of six new species of bees , six new species of flies, five new species of leafhopper and planthopper insects , one new species of wasp and one new species of beetle (Nature Conservancy 199 6). None of the new species were found in potential TWRS areas. However, The Nature Conservancy project focused on the FEALE Reserve, the North Slope, and along the Columbia River rather than in areas of the Site where TWRS activities may occur under the various EIS alternatives.

Table I.4.3.4 lists the relative abundance (percentage) of insect taxa collected from three shrub species on the Site. Grasshoppers and darkling beetles represent some of the more conspicuous insect groups. The populations of both of these species of insects are subject to seasonal changes and weather variations (Rogers-Rickard 1977). Fifty percent of the known insect species are of the order Coleoptera (beetles) (ERDA 1975). Many of the insect species are important in the food web of birds and mammals found onsite. Species like the darkling beetle play an important role in the decomposition process by feeding on decaying plant material, animal excrement, fungi, and live plant tissue (Weiss-Mitchell 1992).

Table I.4.3.4 Relative Abundance of Insect Taxa Collected from Sagebrush, Rabbitbrush, and Hopsage

I.4.4 AQUATIC ECOLOGY

Aquatic habitats on the Hanford Site are primarily associated with the Columbia River, two small spring-fed streams on the FEALE Reserve, and artificial ponds and ditches occurring in or near the 200 Areas. Past studies (Cushing-Watson 1974, Emery-McShane 1978, and Cushing 1994) describe the ecology of some of these ponds. The Columbia River supports a large and diverse community of plankton, benthic invertebrates, fish, and other communities. The springs are also diverse and productive (e.g., dense watercress blooms and fairly high aquatic insect populations). The artificial ponds and ditches, many of which are now abandoned and dried out, often provide lush riparian habitat and support populations of migratory and breeding birds, particularly waterfowl. No extensive discussions are provided of Site aquatic habitats because none of them are in close proximity to any TWRS sites.

I.4.5 SENSITIVE HABITATS

Sensitive habitats on the Hanford Site include wetlands and riparian habitats. Wetlands include those transitional lands occurring between terrestrial and aquatic ecosystems where the water table is usually close to the surface or where shallow water covers the surface (Cowardin et al. 1979). The primary wetlands found on the Site occur along the Hanford Reach of the Columbia River and include the riparian habitats located along the river shoreline. Other wetland habitats found on the Hanford Site are associated with man-made ponds and ditches. These include B Pond and its associated ditches located near the 200 East Area. The B Pond Complex was constructed in 1945 to receive cooling water from facilities in that area. Wetland plants occurring along the shoreline of B Pond include herbaceous and woody species such as showy milkweed (*Asclepias speciosa*), western goldenrod (*Solidago occidentalis*), three square bulrush (*Scirpus americanus*), horsetail (*Equisetum*sp.), rush (*Juncus* sp.), common cattail (*Typha latifolia*), mulberry (*Morus alba*), silver poplar (*Populus alba*), black cottonwood (*Populus trichocarpa*), and willow (*Salix* sp.) (Sackschewsky et al. 1992). Wildlife species observed at B Pond include a variety of mammals and waterfowl species (Meinhardt-Frostenson 1979).

I.4.6 SPECIES OF CONCERN

Species of concern on the Hanford Site include Federally-listed threatened and endangered species, Federal candidate species, Washington State threatened or endangered species, State candidate species, State monitor species, State sensitive plant species, and species of ethnobiological concern to Native Americans.

Species of concern occurring on the Hanford Site are listed in Tables I.4.6.1 and I.4.6.2, along with definitions of each category. No Federally-listed threatened or endangered plant or animal species occur in the 200 Areas, at the potential Pit 30 borrow site located between the 200 East and 200 West Areas, or at the potential Vernita Quarry and McGee Ranch borrow sites. (Sackschewsky et al. 1992). Pipers daisy (*Erigeron piperianus*), a State sensitive species, has been found at B Pond near the 200 East Area and at Pit 30. The crouching milkvetch, stalked-pool milkvetch, and scilla onion, all State Class 3 monitor species, are also found in the 200 East Area.

Wildlife species of concern observed or considered likely to be found on or near the Central Plateau include the sage sparrow (*Amphispiza belli*), loggerhead shrike (*Lanius Ludovicianus*), and Swainsons hawk (*Buteo swainsoni*). The loggerhead shrike and sage sparrow commonly nest in undisturbed shrub-steppe habitat. The sage sparrow is one of the most common nesting birds on the Hanford Site (Downs et al. 1993). Other bird species of concern that may be found include the burrowing owl, ferruginous hawk, Swainsons hawk, golden eagle, sage thrasher, and prairie falcon (Cushing 1994).

Nonavian wildlife species of concern using the Central Plateau and vicinity include the striped whipsnake (*Mastocophis taeniatus*), which is a State candidate species; the desert night snake (*Hypsiglena torquata*), which is a State monitor species; the northern sagebrush lizard, a Federal Category 2 candidate species, and the pygmy rabbit, a Federal Category 2 candidate and State threatened species (Rogers-Rickard 1977).

Table I.4.6.1 Plant Species of Concern on the Hanford Site

Table I.4.6.2 Wildlife Species of Concern on the Hanford Site

To understand the role of the Central Plateau in terms of ethnobiology, the role of the natural environment in a culture, it is necessary to briefly describe the subsistence life-style of the Native Americans that have long resided in the general area (Hunn 1990). The Native American people that resided along the reach of the Columbia River flowing through what is now the Hanford Site followed a seasonal, migratory life-style, as did the majority of Native American people along the Columbia River. They concentrated on salmon fishing at Priest Rapids in the summer and early fall (June through October) when weather and water conditions combined with salmon migration provided a productive fishery. In the spring, they moved towards the areas now known as Moses Lake and Ephrata to gather roots, at one time a substantial component of their diet. In the late fall, the Native Americans moved to the surrounding mountains to gather berries and hunt. In the winter they returned to lower, warmer, elevations along the river where they over-wintered in semi-permanent long-houses. Although Native Americans followed a well-defined pattern of movement throughout the year, they fished for other species when salmon were not present, hunted whenever the opportunity was available, and gathered available, edible food plants.

Affected Tribes have indicated that big game including elk and antelope were abundant on the Columbia Plateau (CTUIR 1996). Other researchers have indicated that the Columbia Plateau historically did not support large populations of big game and that it is more likely that big game hunting was associated with fall berry-gathering expeditions to areas where larger animals were more abundant (Devoto 1953 and Irving 1976) . Smaller mammals such as the yellow-bellied marmot, Beldings ground squirrel, Townsends ground squirrel, jackrabbits, and cottontails probably made up a large portion of the diet of Columbia Basin Native Americans. This has been substantiated by archeological finds along the Columbia River (Aikens 1993).

Bird species were an additional source of food for Native Americans (CTUIR 1996) . Historically, the Hanford Reach of the Columbia River has been an important waterfowl wintering and breeding area. Waterfowl were netted or shot. Egg collecting probably contributed to the Native Americans diet. Birds and bird parts were used for medicinal purposes or as a part of religious practices. Bird parts were also used as decorations and to fletch arrows. Waterfowl and sage grouse probably made up the bulk of birds used for food (Hunn 1990).

Fish have been and remain an important part of the diet of the Native Americans residing along the Columbia River. Salmon played an important role in their diet, but suckers and other bottom fish are thought to have contributed as much to the diet as did salmon (Hunn 1990 and Aikens 1993).

For the Native Americans that live along the Columbia River, salmon and other fish continue to be an important part of their diet.

Plants have been and remain important to Native Americans along the Hanford Reach. Plants or plant parts provide food, medicine, cordage, building materials, and materials of religious significance. Several dozen plant species at the Hanford Site are considered to have uses in traditional Native American cultures and lifestyles. A number of these plants species were identified in 1994 biological surveys of the TWRS sites in the 200 East Area (Fortner 1994).

I.5.0 CULTURAL RESOURCES

The Hanford Site is abundant in cultural sites, including such items as archaeological sites, districts, and objects; standing historical structures, locations of important historic events; and places, objects, and living or nonliving sites that are important to the practice and continuity of traditional cultures. In most cases, cultural sites are finite, unique, fragile, and nonrenewable (PNL 1989).

Archaeological sites are considered to be substantial if they are eligible for inclusion in the National Register of Historic Places (NRHP). Properties are deemed to be eligible for the NRHP if they are important in American history, architecture, archaeology, engineering, or culture.

Three categories of cultural sites are commonly delineated: prehistoric resources, historic era sites, and ethnographic or traditional cultural sites. Prehistoric sites date from before the time of written records. In the interior Pacific Northwest, prehistory refers to the period of time predating Euro-American contact with the Native American cultures and societies of the region. Historic resources are defined as those sites or properties that were occupied or used after written records became available. Structures must usually be at least 50 years old to be deemed historic. However, those items and structures that were built in support of the Manhattan Project during World War II, as well as those that are representations of the Hanford Site's defense mission during the Cold War must also be considered for historic significance (Harvey 1994). Ethnographic sites (traditional cultural sites with historic or socio-religious affiliations) are locations that are important to the heritage of contemporary communities.

The Hanford Site contains a rich diversity of known cultural sites in all three categories. The Site contains seven NRHP Districts as well as 964 sites and isolated finds representative of prehistoric, historic, and modern eras (Neitzel 1996). The overall condition (i.e., integrity) and thus potential significance of Hanford Site cultural sites is high because the area has had limited public access for over 50 years. This restricted access has saved most archaeological sites from looting and other adverse impacts. Another contributing factor to the importance of the Site's cultural sites is that similar areas along the Columbia River have been inundated by hydroelectric development. The Hanford Site has not experienced this type of development nor the resultant depletion of cultural sites, because the reach of the Columbia River adjacent to the Hanford Site has not been dammed.

The Hanford Site is of particular importance to Native Americans. The Hanford Site is part of the original homeland of a number of Tribal Nations. Although no specific religious sites have been identified at the TWRS sites, Gable Mountain is a traditional cultural property located approximately 3 km (2 mi) north of the 200 Areas that would potentially experience impacts from implementation of TWRS alternatives. Further, it is the view of the affected Tribes that all natural resources, including the Sites groundwater and the Columbia River, are also cultural resources to indigenous people (CTUIR 1996).

Archaeological sites or artifacts in the 200 Areas are scarce. A review of existing data for the TWRS sites in the 200 East Area indicates that 28 cultural resource surveys have been previously conducted (ASI 1994). These surveys included 18 block-tract surveys, 7 linear surveys, and 3 historic well surveys. In all, these surveys covered approximately 1,350 ha (3,400 ac). The number of archaeological sites or artifacts recorded as the result of these surveys is limited. Findings recorded in the areas surrounding and including the TWRS sites in the 200 East Area consist of individual isolated artifacts and four archaeological sites. Cultural resource surveys of the TWRS sites and vicinity conducted in 1994 confirmed the overall scarcity of archeological sites and artifacts in the 200 East Area. These surveys indicate no archeological resources in the 200 East Area that are likely to meet the eligibility criteria for inclusion in the NRHP (PNL 1994a, b, c).

The portion of the 200 East Area where TWRS facilities are proposed includes potentially historic buildings and structures associated with the Hanford Site's defense mission. Some of these may meet NRHP eligibility criteria although they have not yet been evaluated for their historical significance. Evaluations of the buildings and structures in the 200 Areas are expected to be completed by the end of 1996 (Cushing 1995). TWRS implementation is not expected to impact these structures.

The 200 West Area has not been as completely surveyed as the 200 East Area. However, a 1988 project by the Hanford Cultural Resources Laboratory surveyed 50 percent of the undisturbed, previously unsurveyed land in the 200 West Area. This survey recorded a small number of isolated historical and prehistoric artifacts, and one extensive cultural feature that has historical significance, the White Bluffs Road (Chatters-Cadoret 1990). None of these sites or artifacts are near TWRS sites, except the White Bluffs Road.

I.5.1 PREHISTORIC RESOURCES

Current cultural resources survey data for the potential TWRS sites in the 200 East Area indicates an overall low probability for prehistoric materials in these locations. Much of the land surface in the 200 East Area has been extensively disturbed by construction and other development activity.

A previous archaeological survey of all the undeveloped portions of the 200 East Area had indicated no findings of archaeological sites or known areas of Native American interest (Chatters-Cadoret 1990). The 1994 cultural resources surveys of the TWRS site and surrounding areas found only individual isolated artifacts and sites (lithics and historic trashcan scatters) (PNL 1994a, b, c). Surveys of the proposed Phased Implementation alternative site in the easternmost portion of the 200 East Area have identified no archaeological sites or artifacts (Cadoret 1995).

As stated previously, a 50 percent survey of all undeveloped and unsurveyed portions of the 200 West Area recorded no prehistoric sites and one prehistoric artifact (Chatters-Cadoret 1990).

Cultural resources surveys of the potential Vernita Quarry borrow site recorded several prehistoric isolates and prehistoric sites. A number of prehistoric isolates and prehistoric sites were also recorded at the potential McGee Ranch borrow site. No prehistoric materials have been recorded at the potential Pit 30 borrow site. The Vernita Quarry and McGee Ranch sites are considered likely to contain more prehistoric materials (Duranceau 1995). Based on the scarcity of prehistoric resources in and around the 200 Areas, there is little likelihood of finding prehistoric resources at Pit 30.

I.5.2 HISTORICAL RESOURCES

The first Euro-Americans to enter this region were Lewis and Clark, who traveled along the Columbia and Snake rivers during their exploration of the Louisiana Territory from 1803 to 1806. Lewis and Clark were followed by fur trappers who also traversed the area on their way to more productive lands up and down the river and across the Columbia Basin. It was not until the 1860's that merchants set up stores, a freight depot, and the White Bluffs Ferry on the Hanford Reach. Chinese miners began to work the gravel bars for gold. Cattle ranches opened in the 1880's and farmers soon followed. Several small, thriving towns including Hanford, White Bluffs, and Ringold, grew up along the riverbanks in the early 20th century. Other ferries were established at Wahluke and Richmond. The towns, settlements, and nearly all other structures were razed after the U.S. Government acquired the land for the Hanford Site in the early 1940's (PNL 1989 and Cushing 1994).

The historic White Bluffs Road extends northeast-southwest across the northwest corner of the 200 West Area. It was an important transportation route during the mining, cattle ranching, and settlement eras of the 19th century, before Washington became a state. In the early 20th century, the road apparently was the primary northeast-southwest route across what is now the Hanford Site. The route was also used in prehistoric and historic times by Native Americans as a trail that connected Rattlesnake Springs with a Columbia River crossing at White Bluffs (Chatters-Cadoret 1990).

The White Bluffs Road has been nominated for the NRHP, although the segment in the 200 West Area is not considered to be a critical element in its historic value (Cushing 1994). The nomination to the NRHP is still pending. A 100-m (330-ft) easement has been created on either side of the road to protect it from uncontrolled disturbance (Cushing 1994). The CTUIR have indicated that the White Bluffs Road is an important cultural site to Native Americans. The road has been fragmented by recent activities associated with the Hanford Site (CTUIR 1996).

Historic materials from Euro-American settlement activities of the 19th and early 20th centuries have been found at both the potential Vernita Quarry and McGee Ranch borrow sites (Duranceau 1995). The McGee Ranch area has been deemed eligible for nomination to the NRHP as the McGee Ranch and Cold Creek District, in large part because of its historic sites (Cadoret 1995). No historic materials have been recorded at the potential Pit 30 borrow site.

Additional historic materials are likely to exist at both McGee Ranch and Vernita Quarry (Duranceau 1995). There is a low likelihood of important historic sites at Pit 30, although one homestead era structure is located in the area (Cadoret 1995).

Of a more recent historical nature (World War II and the Cold War period) are the nuclear reactors and associated materials processing facilities that now dominate the Hanford Site. The construction of three reactor facilities (100-B, 100-D, and 100-F) began in March 1943 as part of the Manhattan Project. In late 1944, the first reactor (100-B) became operational. Plutonium production began in early 1945 and continued into the post-war period. Plutonium for the world's first nuclear explosion test at the Trinity Site in New Mexico and for the bomb that destroyed Nagasaki was produced at the 100-B Reactor (PNL 1989 and Cushing 1994).

Additional reactors and processing facilities were constructed after World War II during the Cold War. All the reactor buildings constructed during these periods still stand, although many of the ancillary support structures have been removed. Because of its significance in contributing to international and national historical events, the 100-B Reactor has been listed individually on the NRHP and is a National Mechanical Engineering Monument ; approximately 110 other buildings have been evaluated for National Register eligibility. Other Manhattan Project facilities have yet to be evaluated. Until a full evaluation addressing each individual structure is conducted, no statement can be made about NRHP eligibility status. As mentioned in Section I.5.0, evaluation of the historic value of structure and buildings in the 200 Areas is scheduled for completion in 2000 (DOE 1996e) . The Washington State Historic Preservation Officer and DOE have determined that the Hanford Site is a Manhattan Project/Cold War era historical district (Neitzel 1996). The waste storage tanks in the 200 Areas may be considered historically substantial, and documentation of the history and use of examples of the various kinds of tanks (e.g., SSTs, DSTs) will be required (DOE 1996e).

The Advisory Council on Historic Preservation recognizes the need to balance the historic preservation of facilities with operational or health and safety issues. The DOE Richland Operations Office , the Advisory Council on Historic Preservation, and the Washington State Historic Preservation Office have signed a Programmatic Agreement that addresses cultural resources management of the built environment at the Hanford Site (DOE 1996e).

I.5.3 NATIVE AMERICAN RESOURCES

The Hanford Site is situated on lands ceded to the U.S. Government by the Confederated Tribes and Bands of the Yakama Indian Nation and the Confederated Tribes of the Umatilla Indian Reservation. The Yakama Indian Nation and the Confederated Tribes of the Umatilla Indian Reservation occupy reservations within 130 km (80 mi) of the Hanford Site. Until 1942, the Wanapum People resided on land that is now part of the Hanford Site. In 1942, the Wanapum People agreed to move from their residence near White Bluffs to the Priest Rapids Area. The Nez Perce Tribe also has retained rights to the Columbia River under a treaty with the U.S. Government.

The Hanford Site has been occupied by humans since the end of the last glacial period. Over 10,000 years of continuous prehistoric human activity in this largely desert environment is reflected by the extensive archaeological deposits along the river shores. Inland areas with water resources point to evidence of concentrated human activity. Recent surveys also indicate the extensive, although dispersed, use of arid lowlands for hunting. Graves are common in various settings and spirit quest monuments are still to be found on high, rocky summits of the mountains and buttes (Cushing 1994).

As mentioned previously, recent biological and cultural resource surveys of the TWRS sites and nearby areas in the 200 East Area found plant species that are of ethnobotanical significance to Native Americans (e.g., plants used for food or medicinal purposes).

Native Americans have retained traditional secular and religious ties to the Hanford Site. Certain landmarks such as Rattlesnake Mountain, Gable Mountain, Gable Butte, and various sites along the Columbia River are sacred to tribes. Native American people also consider numerous burial sites to be sacred (PNL 1989 and Cushing 1994). No specific sacred sites are known at any of the TWRS sites. However, affected Tribes indicate that other culturally important sites are found within areas that may be impacted by TWRS alternatives (i.e., downgradient in the groundwater, the Columbia River, and areas downwind of possible air releases) (CTUIR 1996).

I.6.0 SOCIOECONOMICS

The socioeconomic analysis focuses on Benton and Franklin counties in Washington State. These counties make up the Richland-Kennewick-Pasco Metropolitan Statistical Area (MSA), also known as the Tri-Cities MSA. Other jurisdictions in Benton County include Benton City, Prosser, and West Richland. Connell is the largest city in Franklin County after Pasco. A number of neighboring counties: Yakima, Walla Walla, Adams, and Grant counties in Washington; and Umatilla and Morrow counties in Oregon are impacted by activities at the Hanford Site. However, because nearly 90 percent of Hanford Site employees live in Benton and Franklin counties, the Site's impacts on these other counties are very small (Serot 1995). Thus, no discussion of baseline conditions in the neighboring counties is provided.

In accordance with Federal environmental justice policy, a discussion is provided in Sections I.6.1.4 and I.6.1.5 concerning the distribution and size of minority and Native American and low-income populations within an 80-km (50-mi) radius of the Hanford Site (Executive Order [EO] 12898). This discussion provides the basis for the required identification of potential disproportionate and adverse environmental impacts of EIS alternatives on minority and Native American populations and low-income populations. The 80-km (50-mi) radius includes counties not otherwise covered in this socioeconomic section because overall Site socioeconomic impacts on these counties are very small. However, this section does identify the minority and Native American population and employment within the Hanford Site's primary zone of socioeconomic influence, the Tri-Cities MSA (Benton and Franklin counties).

Before World War II, the economy in the Tri-Cities MSA was based primarily on agriculture. Since World War II, the Hanford Site has been the largest factor in the local economy. Plutonium production and processing was the primary mission of the Site until 1988 when the Site's mission became waste management and environmental restoration. Basic and applied research became an important secondary mission continuing to present.

Changes in the Hanford Site's mission and the cancellation of a Washington Public Power Supply System project at Hanford in the early 1980's (after only one of three planned nuclear power plants was completed) have had a large impact on the economy of the Tri-Cities MSA, creating boom-bust cycles that have had ramifications for employment, population, housing, and infrastructure. Table I.6.0.1 details Hanford Site employment, Washington Public Power Supply System employment, and total nonfarm employment for the Tri-Cities MSA, together with population in the MSA for 1980 to 1994. The Tri-Cities is currently in the early stages of an economic transition as employment at the Hanford Site declines from its recent peak levels.

I.6.1 DEMOGRAPHICS

This section examines population characteristics in the Tri-Cities MSA and the effects of the Hanford Site on the demographics of the area.

I.6.1.1 Population Trends

Population tended to follow changes in nonfarm employment in the Tri-Cities area during the 1980's and early 1990's (Table I.6.0.1). Between 1981 and 1984, nonfarm employment fell by approximately 11,000 jobs, while population fell by about 6,000. Employment began to increase after 1984 but population continued to fall, hitting a low of 138,300 in 1989. Employment increased until 1987 and then fell in 1988 after the decision to close the last plutonium production reactor (N Reactor). Between 1988 and 1989, however, employment in the Tri-Cities jumped by almost 2,000 (despite a continued decline in Hanford Site employment). When employment began to increase again at the Hanford Site in 1990, population increased by almost 12,000, effectively returning to the 1981 level.

The population trends reflected actual employment in the Tri-Cities MSA and expectations of employment. Once the economy began to grow in the late 1980's, people moved into the area, some because they had jobs but many others because they were searching for work. The population of the Tri-Cities area continued to grow as the Site and total nonfarm employment increased through 1994. Data for 1995 showed total Tri-Cities population continuing to grow, while Hanford Site employment declined and total area nonfarm employment remained virtually unchanged from 1994 (Table I.6.0.1) (Neitzel 1996).

Table I.6.0.1 Population and Employment in the Richland-Kennewick-Pasco MSA, 1980 to 1994

I.6.1.2 Population by Race and Minority Status

Table I.6.1.1 details the 1990 population for Benton and Franklin counties and for comparison provides Washington State population by race and minority status. The data show that minorities are a smaller percentage of Benton County population than in Franklin County or Washington State. The largest minority group in the Tri-Cities MSA is the Hispanic origin group, which makes up 30.2 percent of the population of Franklin County and 7.7 percent of Benton County. African Americans make up 1 percent of population in Benton County and 3.5 percent of Franklin County's population.

The American Indian, Eskimo, and Aleut category (Native Americans) accounts for less than 1 percent of the population in each county.

I.6.1.3 Urban, Rural, and Farm Populations

Benton County has a higher percentage of its population classified as urban (87.2 percent) than Washington State (76.4 percent) as a whole, while Franklin County has a lower percentage of urban residence (72.7 percent) than Washington State. At the same time, Benton County's farm population is more than twice as large as a percentage of total population than for Washington State as a whole (12.6 percent to 5.5 percent). Franklin County's farm population is almost five times as large on a percentage basis (24.9 percent) as Washington State's farm population. Franklin County's nonfarm rural population makes up 30 percent of the county's total population, which is virtually the same as the State's (29.3 percent), while more than twice the percentage in Benton County (13.0 percent). These data suggest the relative importance of farming in Franklin County and to a lesser extent in Benton County, compared to Washington State as a whole.

Table I.6.1.1 Population by Race and Minority Status, 1990

I.6.1.4 Minority and Native American Populations

This section and the following section on low-income populations (I.6.1.5) provide data on the distribution of minority, Native American, and low-income populations within an 80 km (50 mi) radius of the Hanford Site, in accordance with the Federal environmental justice policy (EO 12898).

The data provided are based on the following definitions:

- Minority and Native American population: Individuals identified in U.S. Bureau of the Census data for 1990 as Negro, Black or African American, Hispanic, Asian, and Pacific Islander, Native American, Eskimo, Aleut, and other non-White persons (DOC 1991). The minority population consists of the number of individuals residing in the 80-km (50-mi) radius of the Hanford Site who are members of a minority group.
- Low-Income population: Individuals identified in the U.S. Bureau of the Census data for 1990 as having incomes at or below 100 percent of the poverty level (DOC 1991). The low-income population consist of the number of individuals residing in the 80-km (50-mi) radius of the Hanford Site who have incomes below the poverty level.
- Minority and CTUIR, Yakama Indian Nation, and Nez Perce Tribes and low-income communities: For the purposes of this EIS, minority and Native American and low-income populations were analyzed at the census tract level. All tracts within a 80-km (50-mi) radius of the Hanford Site were included in the analysis. Tracts with a substantial minority or low income population were identified as a community for purposes of

environmental justice analysis. The 80-km (50-mi) area of interest was selected based on guidance from DOE regarding the analysis of environmental justice in NEPA documents and is the same area used for the analysis of environmental and human health impacts in other sections of the EIS.

The first step in identifying minority and Native American and low-income communities was to identify the total population of each group within the 80-km (50-mi) radius area of interest. Native American populations of primary concern include members of the three affected Tribes: the Yakama Indian Nation, the CTUIR, and the Nez Perce Tribe. The second step was to identify the combination of census tracts for each type of community that had a total minority and Native American or low-income population that would total one-half of the total population for the entire area of interest.

For minority populations, census tracts with populations that when combined, totaled one-half of the minority and Native American population for the area of interest, had an average percentage of minority and Native American individuals of 33 percent of the tract's total population. These census tracts were then considered minority and CTUIR, Yakama Indian Nation, and Nez Perce Tribes for the purpose of environmental justice analysis in the EIS (Figure I.6.1.1). For low-income populations, census tracts with populations that when combined totaled one-half of the low-income population for the area of interest had an average percentage of low-income individuals of 22 percent of the census tract's total population. These census tracts were then considered low-income communities for the purpose of the environment justice analysis in the EIS (Figure I.6.1.2).

The 80-km (50-mi) radius surrounding the Hanford Site's Central Plateau had a total minority and Native American population of 86,415 individuals as of the 1990 Census (Table I.6.1.2). The area's minority and Native American population of 19.3 percent greatly exceeds the Washington State average of 13.1 percent. The Hanford Site region's principal minority groups consist of Hispanics. In 1990, Hispanics comprised approximately 14.3 percent (64,300 individuals) of the area's population. The Hispanic population is relatively dispersed throughout the area, although Adams, Franklin, and Yakima counties in Washington State have relatively higher populations of Hispanic residents than do the other counties in the region. The Native American population of the surrounding area was approximately 2.4 percent (10,800 individuals). The Native American population is disproportionately located on the Yakama Indian Reservation in south-central Washington, with smaller concentrations in Benton and Grant counties in Washington. African American (5,200 or 1.2 percent) and Asian (6,100 or 1.4 percent) populations in 1990 within the surrounding area were very small and located predominantly in Yakima, Benton, and Franklin counties in Washington State.

As of the 1990 census, 17 of the 97 census tracts that are contained completely or partially within the 80-km (50-mi) radius of the Hanford Site had minority or Native American populations that exceeded 33 percent of their total tract populations (Table I.6.1.3).

Figure I.6.1.1 Census Tracts Within an 80-km (50-mi) Radius of the Hanford Site with Minority Populations Greater than 33 Percent of the Tract Population

Figure I.6.1.2 Census Tracts Within an 80-km (50-mi) Radius of the Hanford Site with Low-Income Populations Greater than 22 Percent of the Tract Population

Table I.6.1.2 Minority Populations Within an 80-km (50-mi) Radius of the Hanford Site by County (1990 Census)

These 17 census tracts contained less than one in five of the area's total residents, yet approximately 52 percent of the region's total minority or Native American population reside in these tracts. Moreover, in 1990 these 17 census tracts were home to over 6 in 10 of the area's Native American residents and at least 57 percent of the region's Hispanic population. Only 4 of the 10 counties in the area (Yakima, Franklin, Grant, and Adams) have census tracts with high levels of minority or Native American residents compared to the region as a whole. In 1990, Yakima County had 10 of the 17 tracts with a 33 percent or greater minority or Native American population. The highest percentage population of minority or Native American residents was found in census tract 0025, located in Yakima County (71.4 percent).

Geographically, the tracts with disproportionately high minority populations or Native American are located northeast of the Hanford Site in Adams and Grant counties, southeast of the Site in Franklin County, southwest and west of the

Site along the Yakima River Valley in Yakima County, and on the Yakama Indian Reservation (Figure I.6.1.1). Of the remaining census tracts, 49 tracts had 1990 minority and Native American populations of less than 10 percent, 23 tracts had minority or Native American populations under 20 percent, and 9 tracts had minority and Native American populations of between 21 and 33 percent.

Table I.6.1.3 Census Tracts Within an 80-km (50-mi) Radius of the Hanford Site With Minority Populations Greater Than 33 Percent of the Tract Population

Five census tracts (Table I.6.1.4), all located within the Yakama Indian Reservation in Yakima County, Washington have large Native American populations. In 1990, the population of these tracts contained nearly 57 percent of the 80-km (50-mi) radius area's Native American population. As of 1990, these tracts were the only census tracts in the area where the Native American population exceeded 8 percent of the tract population.

Census data are an imprecise tool for determining the exact representation of the Hispanic population. Individuals of Hispanic origin derive from diverse cultures and ethnicities. Racial identification is complicated by the lack of a Hispanic category. Hence, Hispanics select from among the available choices of White, African American, American Indian, or Other. Many select Other, although up to 4 in 10 select a different designation, with the bulk selecting White. For the purposes of this report, the census data for the Other category is used to provide an indication of those census tracts that are disproportionately populated by residents of Hispanic origin. Although the Other category does tend to under report the Hispanic population, it provides a tool of sufficient accuracy to approximate Hispanic population concentrations.

Table I.6.1.4 Census Tracts Within an 80-km (50-mi) Radius of the Hanford with Native American Populations Greater Than 500 Individuals (1990 Census)

All of the 17 census tracts with a minority and Native American population greater than 33 percent had substantial numbers of individuals listed in the Other category (Table I.6.1.5.). In all but three of the tracts, the Other category alone accounted for more than 33 percent of the population of the census tracts. Two of these three tracts are located on the Yakama Indian Reservation and have substantial Native American populations. The third tract is located in Franklin County.

I.6.1.5 Low-Income Populations

Figure I.6.1.2 shows the census tracts within an 80-km (50-mi) radius of the Hanford Site with low-income populations greater than 22 percent of the tract population. The 80-km (50-mi) radius surrounding the Hanford Site had a total low-income population in 1990 of 77,700 (Table I.6.1.6).

The area's low-income population of 17.3 percent greatly exceeded the Washington State average of 10.9 percent. In counties examined within Washington, only Walla Walla, Kittitas, and Benton counties had low-income populations below or slightly above the State-wide average.

All of the remaining counties had low-income populations exceeding the 17.3 percent region average. Franklin County, Washington had a low-income population more than double the State-wide average.

Table I.6.1.5 Census Tracts Within an 80-km (50-mi) Radius of the Hanford With Substantial Other Populations Within a Tract With Greater Than 33 Percent Minority and Native American Population (1990 Census)

In all, 25 of the 97 census tracts that are contained all or in part within the 80-km (50-mi) radius of the Hanford Site had low-income populations in 1990 greater than 22 percent of their total populations (Table I.6.1.7). These 25 census tracts contained less than 3 in 10 of the area's total residents (27.9 percent), yet, more than half of the region's total low-income population lived in these tracts (50.8 percent). All but 4 of the counties, Walla Walla, Kittitas, and Klickitat in Washington, and Morrow County, Oregon, had at least 1 census tract containing at least 22 percent of the low-income population. Adams and Benton Counties in Washington, and Umatilla County, Oregon, had 2 or fewer census tracts with low-income populations greater than 22 percent.

Table I.6.1.6 Low-Income Population Within an 80-km (50-mi) Radius of the Hanford Site by County (1990 Census)

Yakima County had 4 of the 5 tracts with 22 percent or greater low-income population in 1990. The highest percentage population of low-income residents was found in census tract 0001, located in Yakima County (45.4 percent). The 25 tracts had a total average low-income population of more than 31.5 percent. Geographically, the tracts with large, low-income populations (22 percent or greater) are located north and northeast of the Hanford Site in Grant County, southeast of the Site in Franklin County, and southwest and west of the Site along the Yakima River Valley and on the Yakama Indian Reservation in Yakima County (Figure I.6.1.2).

Of the remaining census tracts, 30 tracts had 1990 low-income populations that are less than the Washington State average (10.9 percent), 27 tracts had low-income populations between 11 percent and the average low-income population level of 17.3 percent of the 80-km (50-mi) area, and 15 tracts had low-income populations between 17.3 and 22 percent. Fourteen of the 30 census tracts with low-income populations under the Washington State average are located in Benton County (12 tracts) or in the two Franklin County tracts located closest to Hanford Site transportation access.

I.6.1.6 Household Income

The largest fraction of Franklin County households is in the $15,000 to $24,999 income range (Table I.6.1.8). Benton County has its highest concentration of households in the $35,000 to $49,999 range, as does Washington State as a whole. Benton County incomes are slightly skewed to the higher household income ranges as compared to incomes in Washington State as a whole, while Franklin County incomes are skewed to the lower income ranges. Median household income in Benton County was $41,800 in 1993 , while per capita income was $21,030 . Median household income in Franklin County was $30,525 in 1993 , while per capita income was $17,230 . In 1993 , Washington State median household income was $37,316 , while per capita income was $21,770 .

Table I.6.1.7 Census Tracts Within an 80-km (50-mi) Radius of the Hanford Site With Low-Income Populations Greater Than 22 Percent of the Population (1990 Census)

Table I.6.1.8 Household Income, 1990

Data on persons and families below the poverty level show that for most categories Benton County has the same or slightly higher poverty rates as Washington State (11.1 percent compared to 10.9 percent). In contrast, Franklin County's 23 percent poverty rate is substantially higher than the poverty rates for Washington State and Benton County (Table I.6.1.9). The data on income reflect overall the greater urbanization of Benton County and the effects of the Hanford Site as a large source of specialized technical and professional employment in Benton County.

Table I.6.1.9 Persons and Families Below Poverty Level, 1990

I.6.1.7 Educational Attainment

Benton County residents have approximately the same level of education as residents State-wide while Franklin County residents tend to have a lower level of educational attainment (Table I.6.1.10).

I.6.2 PUBLIC FACILITIES AND SERVICES

The following sections describe public facilities and service systems in the Tri-Cities that potentially could be impacted by implementation of the EIS alternatives. Discussions are provided for public safety, hospitals, electricity and natural gas, sewer, and solid waste. Water supply systems are discussed in Section I.2.3.

I.6.2.1 Public Safety

Public safety services, including police and fire, are provided by a number of jurisdictions in the region. Police protection is provided by the county sheriff departments of Benton and Franklin counties, local municipal police departments (Pasco, Richland, Kennewick, and West Richland), and the Washington State Patrol Division in Kennewick. In terms of total staffing, the local municipal police departments (179 commissioned officers and 76 reserve officers) are considerably larger than the two county sheriff departments, which had 62 commissioned officers and 45 reserve officers in 1995 (Neitzel 1996).

Fire protection in the Tri-Cities area is provided by fire departments in the cities of Kennewick, Pasco, and Richland, a volunteer fire department in West Richland, and three rural fire departments in Benton County.

Table I.6.1.10 Educational Attainment, 1990

Public safety services are also provided at the Hanford Site. In the past the Hanford Patrol has provided security and law enforcement services for the Site. Currently, the Benton County Sheriffs Department is providing law enforcement support. The Sheriffs Department maintains an office in the 300 Area. The Hanford Fire Department has approximately 155 firefighters who are trained to dispose of hazardous waste and fight chemical fires. The Hanford Fire Department has fire stations in the 100, 200, 300, 400, and 1100 Areas of the Hanford Site.

I.6.2.2 Hospitals

There are three large hospitals and four small emergency centers in the Tri-Cities area. Kadlec Medical Center in Richland has 133 beds, approximately 6,000 annual admissions, and operates at 50 percent capacity. Kennewick General Hospital has 70 beds, 4,800 annual admissions, and operates at approximately 44 percent capacity. Our Lady of Lourdes Hospital in Pasco had over 4,400 admissions in 1994 (Neitzel 1996) .

The Hanford Environmental Health Foundation primarily provides risk-management services for the Site; they also provide health screening for workers and respond to emergencies at the Site. The Hanford Environmental Health Foundation currently operates five onsite health service centers including facilities in the 100, 200 East, 200 West, and 300 Areas.

I.6.2.3 Schools

Educational services at the primary and secondary level are provided by four school districts. Kennewick is the largest district, serving approximately 13,000 students in 1994, with nearly 8,700 students in the Richland district, 7,800 students in the Pasco district, and 1,500 students in the Kiona-Benton district (Cushing 1995).

School enrollment has increased over the last few years, with all four school districts operating at or near their capacity during the 1994 school year (Cushing 1995). Despite declining Hanford Site employment, school enrollment in the 1995 school year increased by the following approximate amounts: Richland 0.9 percent; Pasco 1.1 percent; Kennewick 2.6 percent; and Kiona-Benton 5.1 percent (Brown 1995, Foley 1995, Haun 1995, Marsh 1995, Meilour 1995, O'Neil 1995). Portable classrooms are used in the Richland (20 portables) and Pasco (60 portables) school districts. In 1995, the Richland, Kennewick, and Kiona-Benton districts were operating at capacity, while the Pasco district was at capacity for the primary grades but had room for more students at the secondary level (Neitzel 1996).

Post-secondary education in the area is provided by the Columbia Basin Community College and the Tri-Cities branch campus of Washington State University. The fall 1995 enrollments for these schools were approximately 6,700 and 1,200 , respectively (Neitzel 1996) .

I.6.2.4 Electricity and Natural Gas

Electricity in the Tri-Cities is provided by the Benton County Public Utility District, Benton Rural Electrical

Association, Franklin County Utility District, and the City of Richland Energy Services Department. The Bonneville Power Administration, a Federal power marketing agency, supplies all the power that these utilities provide in the local area.

Electrical power for the Hanford Site is purchased wholesale from the Bonneville Power Administration. The Hanford Site electrical distribution system is used to distribute power to the majority of the Site. The city of Richland distributes power to the 700, 1100, and 3000 Areas. This is approximately 2 percent of the total Hanford Site usage. Energy requirements for the Hanford Site exceeded 550 megawatts (MW) during fiscal year 1988 (Cushing 1994). The Site's electrical requirement in 1993 was substantially lower at approximately 57 MW (Cushing 1994).

Natural gas, provided by the Cascade Natural Gas Corporation, serves a small portion of the regions residents. In December 1993, Cascade Natural Gas Corporation had approximately 5,800 residential customers (Cushing 1994).

Hydroelectric, coal, nuclear power, oil, and natural gas fuel the Pacific Northwest's electrical generation system. Hydroelectricity is the primary power source in the region, accounting for approximately 74 percent of the regions installed generating capacity of 40,270 MW, and supplying approximately 56 percent of the electricity used by the region. Coal provides 16 percent of the region's electrical generating capacity (Cushing 1994). The one operating commercial nuclear power plant in the Pacific Northwest (located on the Hanford Site) provides approximately 6 percent of the regions generating capacity.

Throughout the 1980's, the Pacific Northwest had more electric power than it required. However, this surplus has been exhausted and the regional system generates only enough power to meet regional electrical needs. It is estimated that the Pacific Northwest will need an additional 2,000 MW over 1991 consumption by the turn of the century (Neitzel 1996).

I.6.2.5 Sewer

Sanitary waste in the 200 Areas is currently disposed of through septic tanks and drain fields. There are concerns about the ability of the current system to handle projected sanitary waste disposal needs resulting from new facilities, increased personnel, and changing environmental regulations. The planned construction of a central collection and treatment facility in the 200 Areas was canceled due to funding constraints. Future upgrades to 200 Areas septic systems may be needed to meet capacity and regulatory requirements (Harvey 1995).

The major incorporated areas of Benton and Franklin counties are served by municipal wastewater treatment systems and the unincorporated areas are served by onsite septic systems. The city of Richland's wastewater treatment system is designed to treat a total capacity of 1.1E+08 L (30E+07 gal/day). The Richland system processed an average of 7.6 E+07 L/day (2.0E+07 gal/day) in 1994 (Nietzel 1996). The wastewater treatment system for the city of Kennewick is also operating well below capacity. The Kennewick system has a treatment capacity of 8.3E+07 L/day (2.2E+07 gal/day) . In 1994 the Kennewick system processed an average of 3.8 E+07 L/day (1.0E+07 gal/day). The Pasco wastewater treatment system has the capacity to treat 9.5E+07 L/day (2.5E+07 gal/day) , and currently processes an average of 2. 9 E+07 L/day (7.8E+06 gal/day) (Neitzel 1996).

I.6.2.6 Solid Waste

The existing Hanford Site nonradioactive solid waste landfill is expected to reach its capacity in 1996. In October 1995 it was announced that DOE and the city of Richland reached an agreement to send the Site's nonregulated and nonradioactive solid waste to the Richland Sanitary Landfill (DOE 1995k).

The city-operated Richland Sanitary Landfill serves Benton County. The landfill, which receives about 200 tons of solid waste per day, has a current life expectancy of 50 years (Penour 1994). This could be extended to approximately 100 years with design modifications.

The city of Kennewick has a contract with Waste Management of Kennewick for solid waste disposal. Waste Management disposes of the solid waste at the Columbia Ridge Landfill in Arlington, Oregon, a facility with a life expectancy of approximately 50 years (Denley 1994).

The cities of Pasco and West Richland have contracts with Basin Disposal, Inc. for solid waste disposal. Basin Disposal, Inc. disposes of the solid waste at the Roosevelt Regional Landfill in Roosevelt, Washington, a facility with a life expectancy of approximately 40 years (Thiele 1995).

I.6.3 ECONOMY

The Hanford Site is the largest employer in the Tri-Cities area. This is a key factor in the local economy. In 1995 , total nonfarm employment in the area averaged about 72,200 . During the same period, Hanford Site employment was about 15,800 or nearly 22 percent of total nonfarm employment. In addition, other workers who are not included in the data as Hanford Site employees provide goods and services to the Hanford Site or its contractors. Agriculture, food processing, retail trade, and other industries provide substantial economic diversity to the Tri-Cities MSA.

Farm employment averaged about 3,500 jobs in Franklin County in 1992 and 4,200 jobs in Benton County. However, Franklin County farm employment ranged from a high of about 9,000 in June 1992 to a low of 1,100 in January. The range in Benton County was 10,700 in June to 1,900 in December. This range reflects the seasonal nature of farm labor. In addition, many farm workers are migratory workers who come to the area during harvest seasons then move on to other regions. Also, year-to-year changes in farm employment are subject to random variations in weather and agricultural market conditions. Changes in Hanford Site employment do not impact the area's farm employment, and for this reason the following discussion focuses on nonfarm employment only.

I.6.3.1 Industries and Employment

Besides DOE and the Hanford Site contractors, major employers in the Tri-Cities MSA include Siemens Nuclear Power Corporation, Sandvik Special Metals, Burlington Northern Railroad, and the Washington Public Power Supply System. Two other major employers, Iowa Beef Processors and Boise-Cascade, have facilities in Walla Walla County adjacent to Franklin County with many of their employees living and shopping in the Tri-Cities (Cushing 1994).

Table I.6.3.1 shows average annual employment by sector in 1993 and 1995 . Total nonfarm employment was approximately 72,200 in 1995, compared to 72,300 in 1994. The largest sector is services, which includes business services, research services (including most Hanford Site employees), and other services. Other Hanford Site employees are classified in the construction, health services, and business services sectors.

After services, the next largest sector is wholesale and retail trade. The Tri-Cities MSA is the main retailing sector for southeastern Washington State and northeastern Oregon. A number of national retail chains have opened outlets in the MSA in the last few years. Columbia Center in Kennewick is the primary regional shopping mall (Serot 1993).

Government is the third largest sector, including Federal, State, and local governments and public schools. Construction has been a key sector in the past few years because of new housing construction, commercial construction, and construction at the Hanford Site. Food processing is the largest manufacturing industry, followed by chemicals. The services sector in Benton County, which includes most Hanford Site and Hanford-related employment, dominates the economy in the Tri-Cities MSA. The services sector in Benton County accounted for $769 million in wages, or about 43 percent of wages paid in the two counties (Table I.6.3.2). State-wide, services accounted for only 21 percent of wages paid. The average wage in the services sector in Benton County was more than $34,000, compared to $17,000 in Franklin County and $23,000 statewide. The higher wage in the services sector in Benton County reflects the specialized technical and professional work force at the Hanford Site.

Table I.6.3.1 Average Annual Employment by Sector Tri-Cities Area, 1993 and 1995

Average wages were higher in Benton County than in Franklin County except in the wholesale and retail trade sector. In that sector, Franklin County has more wholesale trade, which typically pays higher wages than retail trade. Also, agriculture is a larger share of Franklin County's economy than Benton County's, although Benton County had a somewhat higher level of wages paid.

I.6.3.2 Labor Force

Data on occupations for 1990 show that the Benton County labor force is concentrated in the managerial and professional and the technical, sales, and administrative occupations, each of which accounts for about 30 percent of the work force (Table I.6.3.3). Franklin County has much lower percentages in these categories. Technical occupations and farming, forestry, and fishing (agricultural) occupations each accounts for about 21 percent of the Franklin County labor force. Franklin County also has a higher percentage of workers in the operators, fabricators, and laborers occupational category (17.3 percent) than Benton County (12.0 percent).

Table I.6.3.2 Average Wage by Industry in Benton and Franklin Counties and Washington State, 1992

Table I.6.3.3 Civilian Labor Force by Occupation Group, Sex, Race, and Hispanic Origin, 1990

Hispanics account for 6.9 percent of the Benton County labor force and 46.3 percent of the workers in the agricultural occupational category (Table I.6.3.3). In Franklin County, Hispanics are 28.3 percent of the labor force and 63.2 percent of the workers in the agricultural occupations. At the same time, Hispanics in Franklin County account for over 37 percent of the operators category and almost 28 percent of the precision production, craft, and repair occupations. In Benton County, Hispanics represent about 6 percent of the production occupations and 12 percent of the operators occupations. Among other non-Hispanic minority groups, the agriculture occupations have the smallest representation.

African Americans, who make up 0.9 percent of the labor force in Benton County, account for 1.4 percent of the managerial occupations, while in Franklin County African Americans account for 2.1 percent of the labor force and 2 percent of the managerial occupations. In Benton County, Native Americans account for a larger percentage of the production and operators than their percentage of the total labor force. In Franklin County, Native Americans account for a larger percentage of the managerial and production occupations than of the total labor force.

Asians and Pacific Islanders account for 2 percent of the labor force in Benton County and 2.7 percent of the managerial occupations. The same group accounts for 2 percent of the labor force in Franklin County but only 1.2 percent of the managerial occupations. Service occupations show the highest rate of Asian and Pacific Islander representation in both counties. Women account for 40.4 percent of the labor force in Benton County and 42.7 percent in Franklin county. Women account for 51.5 percent of the managerial and professional occupations in Benton County and 39.4 percent in Franklin County. In the other occupational categories the representation of women is similar or virtually the same in the two counties.

In terms of the Hanford Site (Table I.6.3.4), the Hanford Site's maintenance and operators contractor's work force is approximately 29 percent female, 4 percent Hispanic, 3 percent African American, 2 percent Asian, and 1 percent Native American (Pitcher 1994).

Table I.6.3.4 Hanford Site Management and Operations contractor Workforce Representation by Gender and Ethnic Group, 1994

I.6.3.3 Tax Base

Local government revenues in Benton and Franklin counties come primarily from property taxes and the local share of sales taxes. Other revenues come from fees, fines, forfeitures, and transfers from the State or the Federal government. In 1993, assessed property values were about $3.8 billion in Benton County and $1.3 billion in Franklin County. These assessed values were $500 million more than 1992 assessments in Benton County (15 percent increase) and $86 million more in Franklin County (7 percent increase). These increases reflect both new residential and commercial construction and increasing property values caused by the increased demand for residential and commercial property (Serot 1993).

In 1992, the last year for which complete data are available, taxable retail sales were $1,054 million for Benton County and $400 million for Franklin County. This represents a 14 percent increase for Benton County from 1991 levels and a 16 percent increase for Franklin County. Between 1988 and 1992, combined taxable retail sales for the two counties increased from $992 million to $1,481 million (WSDR 1987-1995). This represents almost a 50 percent increase or about 10.5 percent per year. The increase in taxable retail sales shows the effects of rising employment (leading to more consumer spending), population growth, and a general increase in economic activity (Serot 1993).

I.6.3.4 Housing

The growth in employment and population in the Tri-Cities MSA in the late 1980's and early 1990's created a tight housing market. Between 1988 and 1993, the average price of a single-family home increased from approximately $59,000 to $107,000. This increase occurred despite record levels of housing construction. Housing starts increased from 42 in 1988 to 1,200 in 1993 (Table I.6.3.5). However, recent declines in Hanford Site employment, as well as continued construction, resulted in a softening of the housing market and a decline in housing prices and housing starts in 1995 (TAR 1980-1995). The average home sale price in August 1995 was approximately $101,000, down from $126,000 in August 1994. However, most of the drop in home prices occurred in the upper prices ranges, with sales remaining strong in the $70,000 to $120,000 range. In September 1995, the Tri-City Association of Realtors described the local housing market as healthy (Schafer 1995).

Housing prices and housing starts in the Tri-Cities MSA have responded to changes in economic conditions during the past 15 years. Home prices declined after the termination of the Washington Public Power Supply System construction project in 1982 and then again after the shut-down of the Hanford Site's last production reactor in 1987. However, the Hanford Site cleanup and environmental restoration mission and increasing staffing levels, as well as growth in other sectors of the economy caused housing prices to increase dramatically. Until recently, despite new construction and new residences, first-time home buyers faced both rising prices and the lack of available housing, especially at the lower end of the price spectrum.

Table I.6.3.5 Tri-Cities MSA Home Prices and Housing Starts, 1980 to 1993

The housing problem was compounded by very low vacancy rates and increasing rents in rental housing. A December 1993 survey of apartment complexes in Richland, Kennewick, Pasco, and West Richland showed vacancy rates between 1.0 and 2.3 percent. Overall Tri-Cities housing occupancy rates (both single-family and multiple-unit housing) were approximately 95 percent in 1994 and 1995 (Cushing 1995 and Neitzel 1996).

I.7.0 LAND USE

While the focus in the following land-use section is on the 200 Areas, a brief summary is provided on land uses for the remainder of the Hanford Site as well as surrounding offsite land-use patterns. Also addressed are the future planning efforts of other Federal and State agencies, Tribes, and local governments. Prime and unique farmlands and recreational opportunities also are identified.

I.7.1 PRIME AND UNIQUE FARMLAND

The Farmland Protection Policy Act requires Federal agencies to consider prime or unique farmlands when planning major projects and programs on Federal lands. Federal agencies are required to use prime and unique farmland criteria developed by the U.S. Department of Agriculture's Soil Conservation Service (SCS). Under Farmland Protection Policy Act, the SCS is authorized to maintain an inventory of prime and unique farmlands in the United States to identify the location and extent of rural lands important in the production of food, fiber, forage, and oilseed crops (7 CFR Part 657). The SCS has determined that because of low annual precipitation in southeast Washington State, none of the soil occurring on the Hanford Site would meet prime and unique farmland criteria unless irrigated (Brincken 1994). The specific location of potential irrigable prime or unique farmlands at the Hanford Site has not been determined by the SCS because of the absence of detailed slope information.

I.7.2 EXISTING LAND-USE TYPES AND LAND-USE PLANS

This section discusses 1) existing Site land uses and associated issues based on the Hanford Site Development Plan (HSDP); 2) the Comprehensive Land Use Plan (CLUP) for the Site that was prepared by DOE and released for public comment in August 1996 (DOE 1996c) , and other relevant land-use plans by Federal, State, and local agencies and Tribal Nations; and 3) recreational uses.

I.7.2.1 Hanford Site Development Plan

The HSDP provides an overview of land use, infrastructure, and facility requirements to support DOE at the Hanford Site (DOE 1993e). Although the HSDP is not a formal land use plan, it is the most current available planning document until the Site's CLUP is finalized . DOE has invited Trib al Nations , county and city governments, and other stakeholders to participate in the planning process. A draft of the CLUP was release d for public comment in August 1996. Because the CLUP is not yet final , the following discussion focuses on the HSDP.

The HSDP has a Master Plan section that outlines the future land and the infrastructure needed by Hanford Site missions. The primary objective of the Master Plan has been to develop and maintain the Hanford Site infrastructure to meet ongoing and future program requirements (DOE 1993e). A goal of the HSDP has been to maximize the amount of land available for other beneficial uses, including protecting cultural and biological resources.

The HSDP provides for a compatible land-use transition from offsite agricultural uses in Adams, Grant, Franklin, and Benton counties to passive uses onsite in the FEALE Reserve and the proposed National Wildlife Refuge north of and along the Columbia River. The areas of the Hanford Site nearest to the river are proposed to remain undeveloped, providing an additional buffer area between sensitive natural areas and more intensely developed areas such as the Central Plateau. The HSDP accommodates future intensive uses, such as industrial development and research in the southeast area of the Hanford Site near the urban development of Richland. These more intensive uses are adequately separated from less intensive agricultural uses in Franklin County by the Columbia River. The future land uses are designed to facilitate cleanup, maintain a stable employment and economic foundation, provide energy research and development, continue waste management and disposal activities, and provide environmental protection.

Figure I.7.2.1 identifies the existing land uses on the Hanford Site. The Hanford Site has seven major land-use types:

- Reactor Operations, which involves the development and irradiation of nuclear fuels, fuel fabrication, fuel storage, and reactor plant operations (all operations except storage are currently inactive);
- Waste Operations, which include the treatment, storage, and disposal of radioactive and nonradioactive waste, including waste treatment facility operations, active and inactive tank farms, burial grounds, vaults, and cribs;
- Operations Support, which involves services provided specifically for operations that are primarily industrial;
- Administrative Support, which provides administrative services for overall Hanford Site activities;
- Research and Development and Engineering Development, which includes basic and applied research conducted to advance fundamental scientific knowledge related to Hanford Site activities as well as other major national needs;
- Sensitive Areas, which include environmentally (ecological) or culturally (historical, archaeological, and religious) important areas; and
- Undeveloped Areas, which include areas that have not been developed or have been restored to an undeveloped state. The undeveloped areas also contain sensitive biological and cultural resources.

Figure I.7.2.1 Existing Land-Use Map

Sensitive Areas are the largest portion of the existing land use on the Hanford Site. These include the FEALE Reserve, an area that occupies the entire southwest portion of the Hanford Site. Also included are all the Hanford Site lands north of the Columbia River, lands along the river, Gable Butte, Gable Mountain, and an area along the eastern boundary of the Hanford Site south of the river. The area north of the river, the North Slope, is administered by two separate agencies. The U.S. Fish and Wildlife Service (USFWS) administers the area in Grant County west of the northern point of the Hanford Reach known as the Saddle Mountain National Wildlife Refuge. The Washington State Department of Fish and Wildlife Services administers the area in Grant, Adams, and Franklin counties to the north and east of the Hanford Reach, which is known as the Wahluke Wildlife Recreation Area. These areas are undeveloped, natural wildlife areas.

The FEALE Reserve and the North Slope are being considered by DOE for release. The release of the FEALE Reserve could involve land exchange agreements between DOE and the Bureau of Land Management (BLM). The Yakama Indian Nation also has proposed that they take ownership of the Reserve, as has Benton County. Current considerations for the North Slope involve the proposed National Park Service designation of the area as a National Wildlife Refuge (NWR) to be administered by the USFWS. Benton, Franklin, and Grant county commissioners oppose the proposed designation of the North Slope (Campbell 1995). No final resolution of either of these issues has occurred .

The HSDP contains a Future Land Use Map that presents DOE's 1993 vision of future Site land-use needs (Figure I.7.2.2). The Future Land Use Map was intended for annual updates to reflect mission changes, regulatory decision documents, NEPA documents such as the Hanford Remedial Action EIS and the TWRS EIS, and other appropriate sources (DOE 1993e). However, the Site CLUP, was release d in draft form in August 1996 with final decisions expected in early 1997, will provide an official DOE vision of future Site land uses (DOE 1996c) .

Figure I.7.2.2 Future Land-Use Map

As previously mentioned, a goal of the HSDP has been to maximize the amount of land available for other beneficial uses. Future land-use designations were also based on existing and potential Hanford Site missions and assumptions, and the recommendations of the Hanford Future Site Uses Working Group (HFSUWG 1992). The Reactor Operations, Sensitive Areas, and Administrative Support areas remain unchanged from the existing land-use plan (Figure I.7.2.2).

The Hanford Site consists of 1,450 km^2 (560 mi^2) or 145,000 ha (358,000 ac) of land. Of the total Hanford Site area, the Central Plateau, which has been identified for waste management operations, constitutes 117 km^2 (45 mi^2) or 11,700 ha (29,000 ac) of land. This represents approximately 8 percent of the total Hanford Site area. The Central Plateau would consist of 1) a buffer zone of 49 km^2 (19 mi^2) or 4,900 ha (12,000 ac); and 2) a waste management area of 26 km^2(10 mi^2) or 2,600 ha (6,400 ac). The buffer zone would separate the waste management activities from other areas of the Hanford Site. The 200 Areas would be contained entirely within the waste management area. The

2 2

200 Areas consists of 26 km (10 mi) or 2,600 ha (6,400 ac) of land. This represents approximately 22 percent of the total Central Plateau waste management area and 2 percent of the total Hanford Site.

The Waste Operations area is primarily limited to the 200 Areas. Virtually all proposed TWRS activities except two potential borrow sites would occur in or between the 200 Areas. The 200 Areas have been used to process irradiated nuclear fuel and store the resulting waste. Existing facilities in this area include the PUREX Plant, the Plutonium Finishing Plant, the U Plant, the tank farms, the Central Waste Complex, and the Waste Sampling and Characterization Facility. The PUREX, Plutonium Finishing Plant, and U Plants are being deactivated (DOE 1993e). The 200 Areas are also used for Research and Development and Engineering Development; they also contain meteorological towers.

The future locations of the Waste Operations area remain the same although the overall Waste Operation area has been expanded. This expansion reflects land dedicated to a potential cleanup scenario where Sitewide waste is collected and placed in a central location dedicated to exclusive use as a waste disposal area. This includes relocating waste sites, contaminants, and associated structures such as the 100 Area facilities.

According to the HSDP, the future Operations Support areas will remain unchanged except for closing and reclaiming the borrow pit in the western portion of the Hanford Site. The Research and Development and Engineering Development area has increased substantially to include the majority of the southeastern portion of the Hanford Site. The Undeveloped Areas, which include areas of sensitive ecological and cultural resources, have been reduced in size to reflect the future release and reuse of portions of the Site. DOE is working with a variety of governmental and nongovernmental organizations to ensure protection, preservation, and proper management of Hanford Site ecological and cultural resources.

The National Park Service released a Final EIS in June 1994 that recommended designating the Hanford Reach portion of the Columbia River as a Recreational River under the Wild and Scenic Rivers Act and also proposed designating the North Slope, an upland area north and east of the river, a National Wildlife Refuge (NPS 1994). This proposal would transfer management of the river and a 0.40 km (0.25 mi) strip of land along both shores of the river to the USFWS along with approximately 41,300 ha (102,000 ac) of adjacent lands. Development restrictions are included for protecting cultural resources, threatened and endangered species, water quality, unique scenic geologic features, and Native American access and use. The Secretary of the U.S. Department of Interior has issued a Record of Decision indicating a preference for this proposal. This recommendation has been sent to Congress with the final EIS for consideration (NPS 1994).

Benton, Franklin, and Grant count y commissioners oppose the proposed U.S. Department of Interior recommendation and have offered an alternative approach that would leave the Reach under local government control (Stang 1996b). Various local groups (e.g., the Lower Columbia Basin Audubon Society) and many area residents support the Wild and Scenic Rivers designation. No final decisions have been made.

BLM owned many scattered tracts of land on the Hanford Site prior to transferring those lands to the Atomic Energy Commission for national security reasons in 1943. BLM currently does not own any lands on the Site's Central Plateau. However, BLM owns land that includes the potential Vernita Quarry borrow site.

I.7.2.2 Washington State

Washington State has several land interests onsite. The Washington State Department of Fish and Wildlife currently administers the area of the Hanford Site north and east of the Hanford Reach known as the Wahluke State Wildlife Recreation Area. This area is considered sensitive ecological upland habitat and is part of the Wahluke Slope. Washington State also leases a square parcel in the south-central portion of the Hanford Site between State Route 240 and the Route 2/Route 4 junction. This property is located within the undeveloped area of the Hanford Site.

I.7.2.3 Tribal Nations

The Hanford Site is located on land ceded from the Confederated Tribes and Bands of the Yakama Indian Nation and the Confederated Tribes of the Umatilla Indian Reservation (the Umatilla, Cayuse, and Walla Walla Tribes), based on treaties signed in 1855 (DOE 1992b). The Nez Perce Tribe has treaty rights on the Columbia River under a separate treaty.

I.7.2.4 Local Governments

The Hanford Site is located within portions of Benton, Franklin, Grant, and Adams counties. Other surrounding local jurisdictions include the cities of Richland, West Richland, Pasco, and Kennewick.

Because many of the local jurisdictions existing comprehensive plans are incomplete or outdated, they have been updated recently or are in the process of being updated as mandated by the 1990 Washington State Growth Management Act. Because of its limited recent growth, Adams County is not updating its plan.

The majority of the Hanford Site is located within Benton County and comprises up to 25 percent of the county land. The cities of Richland, West Richland, Kennewick, Prosser, and Benton City are located in Benton County. The unincorporated areas of the county adjacent to the Hanford Site currently have generalized land-use designations for rangeland and undeveloped and dry agriculture. Rangeland activities consist largely of cattle grazing. Undeveloped or vacant land is primarily open space. Dry agriculture, the largest single land use in the county, consists almost exclusively of dryland wheat and summer fallow (BCBCC 1985).

Benton County officials are concerned with the remediation and potential reuse of the Hanford Site because most of the land-use effects resulting from reuse would occur within Benton County. Benton County is in the process of updating its comprehensive plan. The county plan update will include a separate Hanford Comprehensive Plan that will be consistent with the overall county plan (Walker 1995). The County Planning Department has defined three categories of land use for the Site: 1) critical areas (e.g., wetlands, areas prone to landslides, fish and wildlife areas); 2) areas where development could occur only if damaged habitat was replaced or restored; and 3) areas where development could occur with minimal restrictions. Of the potential TWRS areas, the potential Vernita Quarry borrow site is within a defined critical area, and the potential McGee Ranch borrow site is within the land use category that would require replacement or restoration of affected land. The Washington State Department of Fish and Wildlife asked Benton County to designate the McGee Ranch as a critical area (preservation area) (McConnaughey 1996a). All other potential TWRS sites are within areas where only minimal development restrictions would be imposed (Fyall 1996).

Benton Countys proposed Hanford Comprehensive Plan is in the process of review and public hearings before the County Planning Commission and then before the county commissioners. The Hanford Comprehensive Plan is expected to be formally adopted by the end of 1996 (Fyall 1996).

Franklin County is located east of the Hanford Site and includes the city of Pasco. The unincorporated area of the county adjacent to the Hanford Site is rural and sparsely developed (Franklin County 1982). The land-use designation surrounding the Hanford Site, as with most of the county, is agricultural. Franklin County adopted an updated comprehensive plan in April 1995. The updated plan does not directly impact any land uses at the Hanford Site (German 1995).

Grant County is located north of the Hanford Reach and includes the Area of the Hanford Site north of the river. The land uses adjacent to the Hanford Site are designated as agricultural (Grant County 1994). This use type is restricted to crop agriculture, agricultural related industries, livestock, and public utility functions (Grant County 1988). Grant County is in the process of updating its comprehensive plan with an expected completion date in 1998 . However, no changes in the county plan would impact areas of the Hanford Site south and west of the Columbia River, which include all potential TWRS areas, because those areas are not within Grant County (Lambro 1996).

Adams County is located northeast of the Hanford Site although a small portion of the Site is located within Adams County. The land use adjacent to the Hanford Site within Adams County is designated as agricultural (Caputo 1994). These lands are either being used for rangeland or are lying fallow.

The city of Richland is located immediately adjacent to the Hanford Site. Richland is currently in the process of annexing the Site's 1100 Area (Milspa 1995). The existing land uses within Richland near the Hanford Site include industrial, agricultural, and public lands. The planned land use designation within the Richland area adjacent to the Site is identified as industrial (City of Richland 1988). Industrial use is compatible with the adjacent Site use. The city develop ed a set of alternatives for its updated comprehensive plan ; these alternatives were released for public review in March 1996 . The comprehensive plan itself is scheduled for adoption in early 1997 (Milspa 199 6). With respect to the Hanford Site, the Richland plan focuses only on the southern portions of the Site, which are within the city's 20-year growth boundaries. The various alternatives being considered for the updated plan would be expected to call for maintaining and expanding industrial and research and development activities in the areas of the city adjacent to the site (Milspa 1996).

West Richland is located to the south of the Hanford Site and is one of the closest developing residential communities. The West Richland land use near the Hanford Site is designated low-density residential (West Richland 1994). This use is consistent with the nearby existing uses (FEALE Reserve and Undeveloped Area) at the Hanford Site. The West Richland Comprehensive Plan update was released in June 1996 and is expected to be adopted in September 1996 . There is little in the update that would impact Hanford Site land-use issues (Corcoran 199 6).

Pasco is located southeast of the Hanford Site and includes the Tri-Cities Airport, which is the area's primary airport. Pasco has been planning major commercial, industrial, office, and residential improvements along the Interstate 182 corridor to attract future Hanford Site-related and other businesses (McDonald 1994). Pasco adopted its updated comprehensive plan in August 1995. However, very little in the update is related to Hanford Site land-use issues (McDonald 1995).

Kennewick is located south of the Hanford Site and is separated from the Site by the Yakima River and the city of Richland. Like Pasco, Kennewick has been planning additional industrial and office areas to attract new businesses. Kennewick adopted its updated comprehensive plan in April 1995. Very little in the updated plan is related to Hanford Site land uses (White 1995).

Another local agency that could be impacted by remediation and reuse of the Hanford Site is the Port of Mattawa. The Port of Mattawa is located in Grant County, northwest of the Hanford Site. The Port of Mattawa is a local government agency obligated to enhance the economic development within District No. 3 of Grant County (Connelly 1994). The Port of Mattawa supports the Wahluke 2000 Plan, which proposes, with U.S. Bureau of Reclamation assistance, to expand irrigated farming acreage and increase recreation uses while protecting wildlife habitat (Wahluke 1994). The Wahluke 2000 Plan represents a different approach than the one outlined by the Park Service (in the Hanford Reach EIS), which has proposed a Recreational River status under the Wild and Scenic Rivers Act for the Hanford Reach of the Columbia River.

I.7.2.5 Natural Resources Trustees Council

The Hanford Site Natural Resources Trustees Council is composed of representatives from the States of Washington and Oregon, Federal agencies (DOE and Interior), and three affected Tribal Nations (Yakama Indian Nation, CTUIR, and Nez Perce Tribe). The primary purpose of the Council is to facilitate the coordination and cooperation of the trustees in their efforts to restore and minimize impacts to natural resources injured as a result of or during cleanup of releases associated with DOEs activities at the Hanford Site. The Councils primary role with respect to the TWRS project will be to consult with DOE during development of the Mitigation Action Plan for impacts identified in the TWRS EIS.

I.7.3 RECREATIONAL RESOURCES AND THE NATIONAL ENVIRONMENTAL RESEARCH PARK

For the purposes of wildlife management and outdoor recreation, some portions of the Hanford Site are administered by agencies other than DOE. The entire Hanford Site was designated by DOE as a National Environmental Research Park in 1976 (NPS 1994). National Environmental Research Parks are aimed at original research into the ecology and natural sciences of an area. Nearly one-half of the Site is designated for use as wildlife management (Figure I.7.3.1).

These wildlife management areas buffer developed areas of the Site. They are the FEALE Reserve, Saddle Mountain NWR, Wahluke Wildlife Recreation Area, Rattlesnake Slope Wildlife Area, and McNary NWR. Ecological data have been collected on these sites for more than 40 years.

I.7.3.1 Fitzner Eberhardt Arid Lands Ecology Reserve

The FEALE Reserve is located in the southwest corner of the Hanford Site. Currently, all research activities on the FEALE Reserve are funded by DOE. Consisting of 310 km^2 (120 mi^2) including Rattlesnake Mountain, the FEALE Reserve is managed for DOE by the Pacific Northwest National Laboratory.

BLM is also involved in the FEALE Reserve. In July 1993, BLM proposed exchanging sections of the Hanford Site with DOE for the FEALE Reserve. BLM propose d to continue management of the FEALE Reserve for its wildlife benefits and to designate it a National Conservation Area. The Yakama Indian Nation also proposed assuming control of the Reserve, with an emphasis on wildlife management, as well as use for Native American cultural purposes. In addition, Benton County has proposed taking over the FEALE Reserve (Stang 1996a).

In July 1996, DOE notified the Yakama Indian Nation, other Federal agencies, and Benton County of its decision to keep control of the Reserve (O'Leary 1996). The Reserve will continue to function as a buffer zone for ongoing waste management in the 200 Areas. DOE also announced its intention to negotiate an agreement with the U.S. Fish and Wildlife Service to manage the Reserve while protecting the ecologically sensitive area and allowing greater public access (Stang 1996c).

Figure I.7.3.1 Recreation and Wildlife Areas and the Hanford Reach

I.7.3.2 McNary National Wildlife Refuge

The McNary NWR, located near the confluence of the Columbia and Snake Rivers, includes three divisions: Burbank Slough, Strawberry Island, and Hanford Islands (Figure I.7.3.1). Only the Hanford Islands Division is within the boundaries of the Hanford Site. The Hanford Islands Division contains six islands in the Columbia River and is located upstream from the city of Richland.

The Hanford Islands extend a distance of 14.5 river km (9 river mi) and contain 140 ha (350 ac). The islands are closed to the public during waterfowl nesting season to protect breeding waterfowl, particularly aleutain canada geese, a Federal and State endangered species.

The McNary NWR was established in 1955 by a cooperative agreement with the U.S. Army Corp of Engineers, which transferred administrative control of nearly 1,200 ha (3,000 ac) of land to the USFWS. Additional acquisitions have enlarged the refuge to the present area of 1,300 ha (3,300 ac). Recreation activities include fishing, picnicking, swimming, and water skiing.

I.7.3.3 Saddle Mountain National Wildlife Refuge

The USFWS manages Saddle Mountain NWR, located on the Hanford Site north and west of the Columbia River (Figure I.7.3.1). Currently, the area is closed to all public use and is dedicated to wildlife management. The USFWS monitors the area for waterfowl populations, kestrel nesting activity, and raptor activity.

The Saddle Mountain NWR was established in 1971 by DOE through a joint agreement with the USFWS. The NWR is located north of the Columbia River from the center of the Hanford Reach to the western boundary of the Hanford Site. The area is currently controlled by DOE but will be transferred to the USFWS upon cleanup of its contaminated sites.

I.7.3.4 Wahluke Wildlife Recreation Area

The Washington State Department of Fish and Wildlife manages the Wahluke Wildlife Recreation Area, located on the Hanford Site north and east of the Columbia River (Figure I.7.2.1). The Wahluke Wildlife Recreation Area is open for public recreation. More than 41,000 people used the area and nearby facilities between July 1988 and July 1989, the most recent year for which statistics are available. More than half of this use took place at the Vernita boat launch, an unimproved launch area immediately upstream of the Vernita Bridge. The Washington State Department of Fish and Wildlife leases approximately 34 ha (85 ac) of Wahluke Wildlife Recreation Area to various private operations for agricultural sharecropping.

I.7.3.5 The Hanford Reach (Proposed Wild and Scenic River Designation)

As the last free-flowing segment of the Columbia River, the Hanford Reach has been proposed for Wild and Scenic River status. The Hanford Reach extends from river mile 396 downstream to river mile 345 and includes those portions of the Columbia River within the boundaries of the Hanford Site. The Hanford Reach boundaries include a 0.4-km (0.25-mi) strip of land on each side of the river, the Saddle Mountain NWR, and the Wahluke Wildlife Recreation Area (Figure I.7.3.1). Designation as a Recreational River (the least restrictive designation under the Wild and Scenic Rivers Act) would provide permanent protection for salmon and cultural resources, enhance wildlife habitats and populations, and improve access and natural resource interpretation for visitors. The USFWS would be designated as the administrating agency. All lands within the proposed boundary would be transferred to USFWS (NPS 1994).

Benton, Franklin, and Grant count y commissioners oppose designating the Hanford Reach as a Wild and Scenic River and have offered an alternative proposal that would provide for local government rather than federal control of the Reach (Stang 1996a). Other local residents support the Federal Wild and Scenic River designation. No final decisions have yet been made.

1.7.3.5.1 Recreational Use

The Hanford Reach and adjacent wildlife refuge and recreation areas provide a variety of recreational activities year-round for local residents and visitors. The most popular activities are sport fishing, boating, and waterfowl hunting, which are considered substantial in terms of impact on the local economy. Other popular activities include waterskiing, upland hunting, and nature observation. The heaviest use period occurs during September and October, coincident with runs of fall chinook salmon. Hunting occurs in areas downstream of the Hanford Townsite from mid-October until late January each year. Nature observation is most popular during autumn and winter months when the greatest number and diversity of migratory and wintering waterfowl species are present.

Because of restricted use of the Hanford Site and Saddle Mountain NWR lands, virtually all land-based recreation occurs on the Wahluke Wildlife Recreation Area. Water-based recreation is supplemented with boating that originates from areas downstream of the Hanford Site. However, the distance from Richland boat launches to key fishing and sightseeing locations suggests that boating accounts for less than 20 percent of water-based use within the Hanford Reach. Total current recreational use of the Hanford Reach comprises approximately 10,000 land-based visits by hunters, trappers, and nonconsumptive users and approximately 40,000 visits by water-based users (predominantly anglers) per year (NPS 1994).

I.7.3.5.2 Sport Fishing

The Hanford Reach is enjoyed by sport fisherman throughout the Pacific Northwest. Steelhead, sturgeon, and smallmouth bass are the primary sport fish. Of these species, the fall chinook salmon and steelhead are regionally important recreational resources, and the Hanford Reach is one of the leading sport salmon fishing areas along the Columbia River.

I.7.3.5.3 Waterfowl Hunting

Waterfowl hunting is the primary hunting activity in the Hanford Reach. The abundance of waterfowl and availability of favorable hunting conditions make the Hanford Reach a regionally important resource.

I.7.3.5.4 Boating

Although much of the boating along the Hanford Reach is related to fishing or waterfowl hunting, scenery, wildlife, and opportunities for solitude make the area increasingly attractive for recreational boaters. An analysis of flat-water boating rivers throughout Washington State, conducted as part of the Pacific Northwest River Study, identified the Hanford Reach as a regionally important boating resource (NPS 1994).

I.7.3.5.5 Nature Observation

The Hanford Reach and surrounding lands provide some of the best opportunities for viewing wildlife in eastern Washington State. Bald eagles, loons, pelicans, terns, gulls, great blue herons, mule and white-tailed deer, coyotes, and beavers are some of the larger species that may be observed. Bird-watching opportunities are optimal during winter months when the Hanford Reach is visited by many species of wintering birds and migratory waterfowl (NPS 1994).

I.7.3.5.6 Swimming

Swimming occurs locally from approximately Memorial Day to Labor Day. Visitors either swim from boats or from the shoreline. There are, however, no developed beaches or designated public swimming areas within the boundaries of the Hanford Site.

I.7.3.5.7 Waterskiing

Waterskiing typically occurs south of the Hanford Site in the vicinity of the city of Richland from mid-May to mid-September. Occasionally, water-skiers travel into the Hanford Reach north of Wooded Island in the vicinity of the Hanford Dunes.

I.7.3.5.8 Other Activities

A relatively small number of people pursue recreational activities within or adjacent to the Hanford Reach. Some activities such as off-road vehicle use, collecting artifacts, and camping are illegal and can be detrimental to the landscape and resources. Off-road vehicle use in the vicinity of White Bluffs has caused considerable damage in some areas and collecting artifacts is an ongoing problem throughout the Site. Camping is permitted at the Ringold boat launch, but occurs illegally at times along other parts of the Hanford Reach shoreline and on some of the islands. The sand dunes are sometimes used by shoreline swimmers, although this is a no-access area (NPS 1994).

I.7.3.6 Rattlesnake Slope Wildlife Refuge

The Rattlesnake Slope Wildlife Refuge is located adjoining the FEALE Reserve's southern boundary. The Refuge, which is managed by Washington State, is outside the boundary of the Hanford Site.

I.8.0 VISUAL RESOURCES

Visual resources reflect the importance of a landscape for its natural or man-made aesthetic qualities and for its sensitivity to change. Landscape character and potential viewing areas are primary factors to be considered in describing the Hanford Site's visual resource values.

I.8.1 LANDSCAPE CHARACTER

The landscape setting within the Hanford Site region is characterized by broad basins and plateaus interspersed with ridges, providing wide, open vistas throughout much of the area. Only about 6 percent of the Site has been disturbed. The remainder of the Site is undeveloped, including natural areas and abandoned agricultural lands that remain undisturbed because of restricted public access.

The major landscape feature of the Hanford Site is the Columbia River, which flows through the northern part of the Hanford Site and turns south, forming the eastern Hanford Site boundary. North of the Columbia River, the Saddle Mountains border the Hanford Site. The Yakima River is located along a small portion of the southern boundary and joins the Columbia River in the city of Richland on the southeastern border of the Hanford Site. Yakima Ridge and Umtanum Ridge form the western boundary of the Hanford Site. Two small east-west ridges, Gable Butte and Gable Mountain, rise above the Central Plateau of the Hanford Site. Adjoining lands to the north, east, and west are principally used for range and agriculture.

The primary focus of the proposed TWRS activities under all EIS alternatives would be in the interior of the Site on the large, flat, open, and semi-arid Central Plateau. Two potential borrow sites, Vernita Quarry and McGee Ranch, are located northwest of the Central Plateau. A third potential borrow site, Pit 30, is located on the Central Plateau between the 200 East and 200 West Areas. The dominant visual features of the Central Plateau vicinity include Gable Butte and Gable Mountain to the north, Rattlesnake Mountain to the south, and Umtanum Ridge to the west.

I.8.2 POTENTIAL VIEWING AREAS

For purposes of study and mapping, viewing areas are generally divided into four distance zones; the foreground, within 0.8 km (0.5 m); the middleground, from 0.8 km to 8 km (0.5 to 5 mi) ; the background, from greater than 8 to 24 km (5 to 15 mi) ; and seldom seen areas that are either beyond 24 km (15 mi) or are unseen because of topography (Figure I.8.2.1).

Hanford Site facilities can be seen from elevated locations such as Gable Mountain, Gable Butte, and Rattlesnake Mountain, which are used by Native Americans for religious purposes, and from offsite locations including State Routes 240 and 24 and the Columbia River. Because of terrain features, distances involved, the size of the Hanford Site, and the size of the individual facilities, not all facilities are visible from the highways or the Columbia River.

Facilities in the 200 East Area are in the interior of the site and cannot be seen from the Columbia River or State Route 24. Large facilities in the 200 East Area may be visible from State Route 240 only as distant background more then 8 km (5 mi) away. Facilities in the 200 West Area can be seen by travelers on an approximately 11 km (7 mi) segment of State Route 240 south of the Yakima Barricade. For these viewers the facilities are in the visual middleground (0.8 to 8 km [0.5 to 5 mi] away). Facilities in the 200 West Area cannot be seen from the Columbia River. Facilities throughout the 200 Areas are visible from elevated locations such as Gable Mountain, Gable Butte, and Rattlesnake Mountain.

Figure I.8.2.1 Viewing Areas of 200 East and 200 West Areas

The potential Vernita Quarry borrow site is situated on a basalt outcrop immediately adjacent to State Route 24. The basalt resource is exposed in basalt cliffs adjacent to the highway and past quarry operations are highly visible. Quarry activities at the site would be visible from the Vernita Bridge, the Hanford Reach, and the Wahluke Slope north of the Columbia River. The quarry would also be readily observed from State Route 24 leading south from the Vernita Bridge. The potential McGee Ranch borrow site would be located west and north of State Route 24 in slightly rolling terrain. The borrow site would be readily visible from State Route 24 south and east of the borrow site. The potential Pit 30 borrow site is located between the 200 East and 200 West Areas and is only visible offsite from elevated locations.

I.9.0 NOISE

Noise as defined by Washington State constitutes the intensity, duration, and character of sounds from any and all sources (WAC 173-60). Sound is produced when a noise source induces vibrations into the surrounding air causing fluctuations in atmospheric pressure. Decibels (dB) are units of sound pressure used to measure changes in atmospheric pressure caused by the vibrations. Primary factors that influence the measurement of noise in ambient air are frequency and duration. The normal human auditory system cannot clearly discern sounds below 100 Hz (hertz or Hz is a measure of frequency or pitch) or substantially above 10,000 Hz. Sound occurring outside this range is not generally perceived as noise. Researchers have developed an A-weighted noise scale (dBA) to describe sounds emanating in those frequencies that are most readily detected by normal human hearing. Table I.9.0.1 lists some common levels of sound and their corresponding dBA levels. Sound duration is another important factor in determining cumulative noise impacts. Noise levels often are reported as the equivalent sound level (L_{eq}) and expressed as a weighted average (dBA) over a specified period of time; the L_{eq}integrates noise levels over time and expresses them as steady-state continuous sound levels.

I.9.1 REGULATORY CONTEXT AND PREVIOUS NOISE STUDIES

The Hanford Site (including its unoccupied areas) is classified as a Class C Environmental Designation for Noise Abatement by Washington State on the basis of industrial activities (Table I.9.1.1). Because they are neither Class A (residential) nor Class B (commercial), unoccupied Hanford Site areas are also classified as Class C areas.

Because of the remoteness of the Hanford Site, only a limited number of studies have been conducted that document environmental noise levels. Two sources of measured environmental noise at Hanford Site are 1) measurements made in 1981 during Hanford Site characterization of the Skagit/Hanford Nuclear Power Plant Site; and 2) noise measurements at five Hanford Site locations performed in 1987 as part of the Basalt Waste Isolation Project.

I.9.1.1 Skagit/Hanford Studies

During preconstruction measurements of environmental noise associated with the Skagit/Hanford Nuclear Power Plant Site, 15 sites were monitored and noise levels ranged from 30 to 65 dBA (L_{eq}). The values for isolated areas ranged from 30 to 38.8 dBA (L_{eq}). Measurements taken at the proposed reactor sites ranged from 50.6 to 64 dBA. Measurements taken along the Columbia River near the proposed intake structures were 47.7 and 52.1 dBA, as compared to noise levels of 45.9 dBA measured at a more remote location about 5 km (3 mi) upstream from the intake structures. By comparison, community noise levels in North Richland (at Horn Rapids Road and the Bypass Highway) were 60.5 dBA (NRC 1982).

Table I.9.0.1 Common Sounds and Corresponding Noise Levels

Table I.9.1.1 Applicable State Noise Limitations for the Hanford Site [1]

I.9.1.2 Basalt Waste Isolation Project Studies

As part of the investigation for proposed Basalt Waste Isolation Project at the Hanford Site, background noise levels were determined at five locations. Noise levels can be expressed as L_{eq} for 24 hours (L_{eq}-24). Based on information provided in Cushing (Cushing 1994), wind was identified as the primary contributor to background noise levels with winds exceeding 19 km/hr (12 mi/hr), substantially impacting noise levels. As a result, it was concluded that background noise levels in undeveloped areas at the Hanford Site can best be described as having a mean L_{eq}-24 of 24 to 36 dBA. Periods of high wind, which normally occur in the spring, would elevate background noise levels.

I.9.1.3 Noise Levels of Hanford Field Activities

To protect Hanford Site workers and to comply with Occupational Safety and Health Administration standards for noise in the workplace, the Hanford Environmental Health Foundation monitors noise levels resulting from routine operations performed at the Hanford Site (DOE 1991 and Cushing 1992). Occupational sources of noise propagated in the field are summarized in Table I.9.1.2. These levels are reported because operations such as well sampling are conducted in the field away from established industrial areas and have the potential for contributing to environmental noise and disturbing sensitive wildlife.

Table I.9.1.2 Monitored Levels of Noise Propagated from Outdoor Activities at the Hanford Site[1]

I.9.2 HANFORD SITE NOISE CONDITIONS

Existing noise conditions produced by current, routine operations at the Hanford Site do not violate any Federal or State standards. Measurements show that even near the current operating structures along the Columbia River noise levels are less than experienced in part of the community of Richland (less than 52.1 dBA versus 60.5 dBA). Noise levels measured near intake structures at the Columbia River are well within the 60 dBA tolerance levels for daytime residential use. Five km (3 mi) upstream of the intake structures noise levels fell well within levels suited for daytime and nighttime residential use.

Moreover, the remoteness of the main areas of Hanford Site industrial activities from population centers means that there are no offsite populations within auditory range of Site industrial activities. However, Affected Tribal Nations use Site locations such as Gable Mountain for religious purposes.

I.10.0 TRANSPORTATION

The Tri-Cities area is served by air, rail, water, and road transportation networks. The majority of air passenger and freight services goes through the Tri-Cities Airport, located in Pasco (Cushing 1992). In addition, two smaller airports serving general aviation aircraft are located in Richland and Kennewick. No airport facilities are located on the Hanford Site.

Water-borne transportation is accommodated by docking facilities at the Ports of Benton, Kennewick, and Pasco (Cushing 1992). The commercial waterways of the Snake and Columbia Rivers provide access to the deep-water ports of Portland, Oregon and Vancouver, Washington. The Port of Benton is the port-of-call for all vessel traffic to the Hanford Site.

The Hanford Site rail system consists of about 210 km (130 mi) of railroad track. Approximately 140 km (87 mi) of the system are considered in service to active Site facilities. Approximately 64 km (40 mi) of track are in standby condition. The standby trackage serves Site areas that have no current rail shipping needs. Although the standby track is not currently maintained, it could be restored if needed. The Hanford Site rail system extends from the Richland Junction (at Columbia Center in Kennewick) south of the Columbia River where it joins the Union Pacific commercial railroad track, to an abandoned commercial right-of-way near the Vernita Bridge in the northern portion of the Site (Figure I.10.0.1). There are currently about 1,400 railcar movements annually Sitewide, transporting a wide variety of materials including fuels (e.g., coal and oil), hazardous process chemicals, and radioactive materials and equipment. Radioactive waste has been transported by rail on the Site without incident for many years (DOE 1995i).

Regional road transportation is provided by a number of major highways including State Routes 240 and 24 and U.S. Interstate Highway 82. State Routes 240 and 24 are both two-lane roads that traverse the Hanford Site. State Routes 240 is a north-south highway that skirts the easternmost side of the FEALE Reserve. State Routes 24 is an east-west highway located in the northern portion of the Hanford Site. These roads are maintained by Washington State (Cushing 1992).

A DOE-maintained road network within the Hanford Site provides access to the various work centers (Figure I.10.0.1). The majority of these roads are paved and are two lanes wide. The primary access roads on the Hanford Site are Routes 2, 4, 10, and 11A. The 200 East Area is primarily accessed by Route 4 South from the east and from Route 4 North off Route 11A from the north and from Route 11A for vehicles entering the Site at the Yakima Barricade. A new access road was opened in late 1994 to provide access directly to the 200 Areas from State Route 240. The 200 West Area is primarily accessed from Route 6 off Route 11A from the north. Public access to the 200 Areas and interior locations of the Hanford Site has been restricted by guarded gates at the Wye Barricade (at the intersection of Routes 10 and 4) and the Yakima Barricade (at the intersection of State Route 240 and Route 11A). None of the previously listed roadways have experienced any substantial congestion except Route 4 (WHC 1994c).

Figure I.10.0.1 Hanford Site Transportation Network

Route 4 carries most of the traffic from the City of Richland to the 200 Areas. Traffic volumes during shift changes at the Hanford Site create severe traffic congestion. July 1994 traffic counts along Route 4 South just to the west of the Wye Barricade showed an average daily traffic (ADT) of approximately 9,200 vehicles, with morning peak hour volumes of nearly 2,400. By mid-1995 with reductions in Site employment, and the opening of the State Route 240 Access Road (Beloit Avenue), morning peak hour traffic had declined to slightly above 1,700 (Rogers 1995). Farther to the southeast, near the 1100 Area where Route 4 becomes Stevens Road, the 1992 ADT was approximately 24,800 with a peak hour volume of over 2,900. Level of Service (LOS) is a qualitative measure of a roadway's ability to accommodate vehicular traffic, ranging from free flow conditions (LOS A) to extreme congestion (LOS F). LOS D is considered the upper end of acceptable LOS. A 1994 report indicated that Route 4 was operating at LOS E and a 1993 report indicated that Stevens Road was operating at LOS F (WHC 1994c and BFRC 1993). The factors indicated previously, namely, Site employment reductions, and the heavy use of the new State Route 240 Access Road (peak hour volume of nearly 900 vehicles by mid-1995), have reduced the traffic congestion in these areas (Rogers 1995).

Traffic counts along Route 11A, which is just to the east of the Yakima Barricade off of State Route 240, show an ADT of approximately 1,260. Traffic counts along Route 10, just to the north of its terminus at State Route 240, show an ADT of approximately 2,440 (WHC 1994c).

I.11.0 RADIOLOGICAL ENVIRONMENT: OVERVIEW AND POTENTIAL RADIATION DOSES FROM 1994 HANFORD SITE OPERATIONS

This section provides a brief introduction to the subject of radioactivity and to some of the common terms used in radiological health evaluation. It also summarizes 1994 data on radiation doses from operations at the Hanford Site and estimates the potential future fatal cancers attributable to these radiation exposures.

I.11.1 INTRODUCTION TO RADIOACTIVITY

Radioactivity is a broad term that refers to changes in the nuclei of atoms that release radiation. Radiation is an energetic ray or energetic particle. For ionizing radiation, the ray or particle has enough energy to cause changes in the chemical structure of the materials it strikes. These chemical structure changes are the mechanisms by which radiation can cause biological damage to humans.

Radiation comes from many sources, some natural and some man-made. People have always been exposed to natural or background radiation. Natural sources of radiation include the sun, and radioactive materials present in the earth's crust, in building materials and in the air, food, and water. Natural radioactivity can even be found within the human body. Some sources of ionizing radiation have been created by people for various uses or as by products of these activities. These sources include nuclear power generation, medical diagnosis and treatment, and nuclear materials related to nuclear weapons.

Radioactive waste is a result of the use and production of radioactive materials. At the Hanford Site, DOE manages radioactive waste that was generated primarily by the production of plutonium for nuclear weapons. These waste is classified as low-activity, high-level, or transuranic. When radioactive waste is combined with hazardous chemical wastes, it is referred to as mixed waste. High-level waste is the most dangerous type of radioactive waste and requires extensive shielding by materials such as lead and concrete and special handling. Transuranic waste is material contaminated with radioactive elements heavier than U. While long lasting, transuranic waste does not require the same degree of isolation as high-level waste. Low-activity waste is generally the least dangerous type of radioactive waste and requires fewer measures to isolate it from people and the environment. Depending on the particular radioactive material involved, radioactive waste can be harmful and thus require isolation for up to hundreds or even thousands of years. Plutonium-contaminated waste will be radioactive for thousands of years. Radioactive Cs, on the other hand, will be virtually gone in 250 years.

I.11.2 COMMON TERMS IN RADIOLOGICAL HEALTH EVALUATIONS

Radiation dose to individuals is usually expressed in rem or millirem (mrem), which is one-thousandth of a rem. The rem is a measure of the biological effects of ionizing radiation on people. It is estimated that the average individual in the United States receives an annual dose of about 300 millirem from all natural sources. The collective radiation dose to a population is termed the person-rem, which is calculated by adding up the radioactive dose to each member of the population.

Any dose of radiation can damage body cells. However, at low levels, such as are received from a medical x-ray, the damage to cells is so slight that the cells can usually repair themselves or can be replaced by the regeneration of healthy cells. Radiation exposures are often classified as acute (a dose received over a short time) or chronic (a dose received over a long time). Chronic doses are usually less harmful than acute doses because the body has time to repair or replace damaged cells; however, even low doses can have harmful effects.

Impacts from radiation exposure often is expressed using the concept of risk. The most substantial radiation-related risk is the potential for developing cancers that may cause death in later years. This delayed effect is measured in latent (future) cancer fatalities. The risk of a latent cancer fatality is estimated by converting radiation doses into possible numbers of cancer fatalities. For an entire exposed population group, the latent cancer fatality numerical value is the chance that someone in that group would develop an additional cancer fatality in the future because of the radiation exposure, (i.e., a cancer fatality that otherwise would not occur).

Radiological risk evaluations often refer to the maximally-exposed individual. This would be the member of the pubic or a worker who receives the highest possible dose in a given situation. As a practical matter, the maximally-exposed individual likely would be a person working with radiological or hazardous materials.

I.11.3 POTENTIAL RADIATION DOSES AND LATENT CANCER FATALITIES FROM 1995 HANFORD SITE OPERATIONS

Each year potential radiation doses to the public are calculated for exposure to Hanford Site effluents. The 1995 information presented here was taken from the Hanford Site Environmental Report for calendar year 1995 (PNL 1996). Doses are calculated from reported effluent releases, from environmental surveillance results, and from information about operations at specific Hanford Site facilities.

The 1995 potential dose from Hanford Site operations to the hypothetical maximally-exposed individual member of the public was 0.02 mrem , compared to 0.05 mrem reported for 1994 (PNL 1996) . The current DOE radiation dose limit for an individual member of the public is 100 mrem per year, and as stated previously, the national average dose from natural sources is 300 mrem per year. Thus, the maximally-exposed individual potentially received a small fraction of 1 percent of both the DOE dose limit and the natural background average dose.

The total population of the surrounding area (380,000 persons) received a potential dose from 1995 Hanford Site operations of 0.3 person-rem. The 1994 average dose to an individual member of the public was 0.0009 mrem. This is 0.001 percent of the 100 mrem/year standard and 0.0003 percent of the 300 mrem per year received from typical natural sources. Clean Air Act requirements specify a maximum radiation dose through the air of 10 mrem per year. The 1995 air emissions from the Hanford Site were 0.006 mrem, which is less than 0.1 percent of the 10 mrem standard.

Based on a dose-to-risk conversion of 0.0005 latent cancer fatalities per rem (each rem equates to 0.0005 latent cancer fatalities), there would be 0.0001 latent cancer fatalities in the general public attributable to exposure to effluents from 1995 Hanford Site operations.

APPENDIX J

CONSULTATION LETTERS

The National Environmental Policy Act (NEPA) and the Washington State Environmental Policy Act (SEPA) implementing regulations require that Federal agencies consult with Federal, State, and local agencies and Tribes (as appropriate) regarding proposed actions addressed in Environmental Impact Statements (EIS). The U.S. Department of Energy (DOE) and the Washington State Department of Ecology (Ecology) have performed this consultation through informal meetings, discussions, and correspondence. DOE and Ecology have provided formal requests for information and consultations to Federal, State, and local agencies and Tribes that may have regulatory jurisdiction or special interest in the issues and alternatives to be addressed in the TWRS EIS. This appendix contains copies of the consultation letters sent by DOE and Ecology to agencies and Tribes and the responses by those agencies and Tribes.

APPENDIX J

APPENDIX K
UNCERTAINTIES ANALYSIS
K.1.0 INTRODUCTION

Uncertainty in risk analysis is a consequence of two factors: lack of data and natural variability (Figure K.1.0.1). The lack of data is reflected in the limited knowledge either about the value of constants, or about the statistical parameters (e.g., distribution shape, mean, variance) of things that are inherently variable (e.g., inhalation rates or body weights). Uncertainty due to the lack of data can be reduced in principle by more accurate measurements. Uncertainty due to natural variability cannot be reduced by improved measurement, but can be better estimated by acquiring data to characterize statistical distributions of measured variables and by using computer programs to simulate the effect of such variability in the components of equations on calculated values (e.g., risk estimates). These combined efforts can reduce systematic uncertainty in the Environmental Impact Statement (EIS) analyses and provide a more thorough understanding of the effects of the remaining uncertainty on the conclusions in the document.

The evaluation of systematic uncertainties is the most difficult aspect of determining the overall uncertainty of an analysis. A systematic error is the difference between the mean of an analysis and the true value. When true value is unknown, the systematic error only can be estimated. The estimated limit of the systematic error is called the systematic uncertainty of the analysis (Catland 1990). The systematic uncertainty is made up of multiple sources of systematic errors, each of which must be evaluated and quantified. When sources of systematic error are found and reduced, the systematic uncertainty is reduced.

Uncertainty in the conclusions of this EIS is a consequence of uncertainty in two major areas: the descriptions of the alternatives, with their associated assumptions about tank waste inventories, composition, and remediation technologies; and the consequences analyses, which include assumptions about waste source and release terms, future land uses, environmental transport parameters, and relationships between exposure and risk (Figure K.1.0.1). This appendix discusses the major sources of uncertainty in each of these areas. In addition, a less conservative (nominal) human health risk analysis is presented to illustrate the

implications of relating some of the conservative assumptions made for the bounding case risk analyses in the EIS.

Section K.2 describes the uncertainties and assumptions in the alternative descriptions, including engineering, schedule, staffing, resources, and costs. Section K.3 discusses uncertainties and assumptions in the source terms and in the release terms for acute (accident) and chronic (routine) scenarios. Section K.4 describes the uncertainties and assumptions in estimating contaminant transport through soil, ground and surface water, and air. Sections K.5 and K.6 present the uncertainties and assumptions in the human health risk exposure assessment and risk characterization, respectively. Section 5.7 describes the results of a less conservative (nominal) human health risk analysis, focusing on the Ex Situ Intermediate Separations alternative as an example. Section K.7 describes the uncertainties in the ecological risk assessment (ERA) and their effects on the conclusions in the EIS.

Figure K.1.0.1 Sources and Types of Uncertainty in the TWRS EIS

K.2.0 UNCERTAINTIES IN ALTERNATIVES

A full range of representative alternatives was developed for detailed analysis in the EIS. Upper, lower, and intermediate bounding alternatives were developed in terms of cost, risk, and technologies for the two primary decisions that affect environmental impacts: the amount of waste to be retrieved from the tanks and the degree of separations of retrieved waste into high-level waste (HLW) and low-activity waste (LAW).

The alternatives developed were chosen to be representative of many possible variations of the alternatives. The design information for all alternatives is at an early planning stage, and the details of the alternative ultimately selected and implemented are likely to change as the design process matures.

Each alternative developed for analysis in the EIS consists of a set of technologies, or building blocks, that have been engineered to work together, forming complete systems for accomplishing the remediation of the tank waste.

Engineering data were developed for each alternative in support of the environmental impact analysis. These data included the following major components:

- Conceptual design of the type and size of facilities required for waste treatment;
- Schedules and staffing requirements (radiological and nonradiological workers) for the construction and operation of waste treatment facilities;
- Resource requirements for the construction and operation of the waste treatment facilities;
- Air emissions for routine tank farm operations, waste treatment operations, and post remediation;
- Contamination releases to the soil during waste retrieval and during the post- remediation phase; and
- Land use requirements, both temporary and permanent, for the construction and operation of waste treatment facilities.

These major components were developed based on certain assumptions, general engineering information, and previous development work. The uncertainties associated with engineering assumptions for each alternative are presented in Section K.2.2, and the uncertainties related to general information such as schedule projection, staffing and resource prediction, and cost estimation are discussed in Sections K.2.3 through K.2.6, respectively.

K.2.1 OVERVIEW

There are many uncertainties associated with the alternatives for remediating the tank waste. These uncertainties involve the types of waste contained in the tanks, the effectiveness of the proposed retrieval techniques, and the processes used to separate and treat the waste. These uncertainties exist because some of the technologies that would be implemented are first-of-a-kind and have not previously been applied to the Hanford Site tank waste, or they have not been applied at the scale required for the tank waste.

K.2.2 UNCERTAINTIES FOR MAJOR ASSUMPTIONS

To develop the engineering data required to perform impact analyses for each of the alternatives discussed in the EIS, assumptions were made regarding the technologies that create a remediation alternative. These assumptions were based on either the best information available, applications of a similar technology, or engineering judgement. When an assumption is made, there is some level of uncertainty associated with it that can be expressed as a range that reasonably could be expected for the assumed value. This section identifies the major assumptions used for the alternatives, describes uncertainties associated with the assumptions, and presents the results of a waste loading sensitivity analysis for the Ex Situ Intermediate Separations alternative.

K.2.2.1 Long-Term Management and In Situ Alternatives

Tank Leakage

It was assumed that there would be no leaks from the single-shell tanks (SSTs) or double-shell tanks (DSTs) during the administrative control period for the No Action, Long-Term Management, or In Situ Fill and Cap alternatives because the ongoing process of removing the pumpable liquids from SSTs was assumed to be completed, and leaks would be recovered from the space between the inner and outer liners of the DSTs. The SSTs and DSTs were assumed to maintain their structural integrity throughout the administrative control period under the No Action and Long-Term Management alternatives. For the Long-Term Management alternative, replacement of the DSTs was assumed to be necessary to prevent leaks.

The uncertainty with this assumption is that a leak could develop or a structure failure could occur, resulting in a release of contaminants during the administrative control period. It is likely that corrective actions would be taken in the event of a leak or signs of structural deterioration. Corrective actions could include waste retrieval and retanking activities to minimize environmental releases. If these activities were to occur, increases in the release of contaminants of the air and vadose zone would be expected.

In Situ Vitrification

The In Situ Vitrification alternative is more conceptual in design and development than the ex situ vitrification alternatives and thus has a higher degree of uncertainty associated with the data developed for impact assessments. The in situ vitrification system was assumed to be capable of vitrifying each of the tanks to the required depth, resulting in a consistent waste form. It also was assumed that the variation in waste composition and inventory from tank to tank would not impact the ability to produce an acceptable waste form.

There is considerable uncertainty about the ability of the in situ vitrification system to vitrify the large volume required for the SSTs and DSTs. This uncertainty could be reduced through the use of smaller vitrification systems and the development of depth-enhancing techniques. This likely would result in increased staffing requirements and longer operating durations.

The air emissions estimates developed for the In Situ Vitrification alternative assumed that the entire inventory of iodine-129 (I-129) would be released to the atmosphere during the operating period. Off-gas treatment systems could be expected to remove part of the I-129 and reduce these emissions.

The long-term waste form performance for the vitrified waste was based on the assumption of a homogeneous waste form with properties similar to the glass produced by the Ex Situ No Separations alternative. Inspecting the final waste form to verify that all of the wastes were vitrified would be difficult and could result in undetected waste form variations. Variability in the waste form or fracturing of the waste form during cooling would be expected to result in increased contaminant release rates to the vadose zone.

The safety of drying some of the waste types is uncertain. Further evaluation of this issue could result in some tanks not being suitable for in situ vitrification.

In Situ Fill and Cap

Under the In Situ Fill and Cap alternative, the DST liquids would be concentrated using the 242-A Evaporator to remove as much water from the waste as possible, but the waste still would contain substantial volumes of liquid. It was estimated that concentration by the 242-A Evaporator would reduce the current liquid volumes contained in the tanks by approximately one-third (WHC 1995f). The concentrated liquid waste contained in the DSTs was assumed to be acceptable for gravel filling.

Additional development of this alternative could result in a requirement for additional liquid removal and drying of the waste in the tanks. If this were to occur, development of an in situ drying technology would be required and its use would result in increased volatile radionuclide and chemical emissions from the tanks, in addition to increases in staffing levels and operating schedule.

K.2.2.2 Ex Situ Alternatives

Waste Retrieval Efficiency

The waste retrieval function described for the ex situ alternatives was assumed to remove 99 percent of the waste volume contained in each tank during waste retrieval. Under this assumption, 1 percent of the tank volume would be left in-tank as residual. It was further assumed that the 1 percent waste volume represented 1 percent of the waste inventory on a chemical and radiological basis including soluble waste constituents. This assumption is conservative and will bound the impact from the tank residuals.

The amount and type of waste that would remain in the tanks after retrieval is uncertain. The Hanford Federal Facility Agreement and Consent Order (Tri-Party Agreement) (Ecology et al. 1994) set a goal for the SSTs that no more than 1 percent of the tank inventory would remain as residual following waste retrieval activities to the extent technically practicable. The engineering data for the waste retrieval and transfer function common to all ex situ alternatives was developed using 99 percent retrieval from SSTs and DSTs as an assumption.

It would be expected that the residual contaminants left in the tanks either would be insoluble and hardened on the tank walls and bottom or be of a size that could not be broken up and removed from the tanks without extraordinary measures. In either case, the residual waste would have low solubility because the retrieval technologies proposed would use substantial quantities of liquid to dissolve or suspend the waste during retrieval.

The effect of retrieving less than 99 percent of the waste volumes from the tanks during retrieval would be an increase in the amount of waste left in the tanks and corresponding increases in long-term contaminant releases. The in situ and combination alternatives would leave substantially more waste onsite for disposal and provide an upper bound on the impacts associated with the amount and type of waste that is disposed of onsite. Retrieval of more than 99 percent of the waste would reduce the impacts associated with residual waste.

A nominal case tank residual inventory was developed to evaluate the impacts that would result from a more nominal residual inventory. The nominal residual inventory was developed by accounting for the solubility of the mobile constituents of concern. The mobile constituents of concern were evaluated because of their contribution to post-remediation risk. The isotopes carbon-14 (C-14), technetium-99 (Tc-99), and I-129 were reduced for the nominal case to 10 percent of the bounding residual inventory. For additional information, refer to Volume Two, Appendix B.

The U.S. Department of Energy (DOE) currently is developing the Hanford Tanks Initiative (HTI) program that will provide information on the characteristics of the tank residuals and the capability of retrieval systems to handle difficult-to-remove SST wastes. This program will reduce the uncertainties associated with residual waste, demonstrate the capability to quantify residual waste volume, and demonstrate technologies for sampling and characterizing the residual waste.

Assumptions Affecting HLW Volume

The major factors that affect the volume of HLW produced by any of the ex situ alternatives include waste inventory, waste loading (glass specifications), blending, and the efficiency of the separations processes. The waste inventory that has been used for all alternatives is provided in Volume Two, Appendix A along with a discussion on data accuracy and uncertainty.

Waste loading is the mass fraction of the nonvolatile waste oxides in the vitrified waste. The waste oxide loading would be controlled by the amount of glass formers added during the vitrification process. The higher the waste loading, the more waste contained in the vitrified glass and the lower the waste volume.

Blending is the mixing of the waste from different tanks during retrieval to obtain an average waste feed stream for treatment. Because there are 177 tanks that contain waste, and the waste composition varies from tank to tank, it would be difficult to achieve a completely uniform blending of the waste during retrieval.

Separating the waste into HLW and LAW streams for treatment would involve various processes to physically or chemically separate specific constituents in the waste stream. The separations efficiency would be a measure of how well these processes work and would define the amount of each constituent that would be processed in the HLW and LAW treatment facilities.

The assumptions used for each of the previously described factors and their combined effect on the overall volume of HLW and LAW are discussed in the following sections.

Waste Loading

The waste loading for all ex situ treatment alternatives, except for the Ex Situ No Separations alternative was assumed to be 20 weight percent waste oxides for the HLW and 15 weight percent sodium oxide (Na_2O) for the LAW. The waste loading for the Ex Situ No Separations alternative was assumed to be 20 weight percent Na_2O.

Waste loading would affect the final volume produced from an initial amount of waste. This volume, along with the operating schedule and the assumed operating efficiency, would determine the size of the processing facilities and operating resources required to support the process. A decrease in waste loading would translate into a larger volume of vitrified waste, larger treatment facilities or longer operating schedules, increased resource requirements, and higher disposal cost.

Waste loading typically ranges from 20 to 40 weight percent waste oxides, with 30 to 35 weight percent loading used as a target value. The Savannah River Site Defense Waste Processing Facility glass has a design basis waste loading of 25 weight percent and a maximum waste loading of 38 percent (DOE 1995s).

The waste loading for all alternatives that would produce LAW was assumed to be 15 weight percent Na_2O. The volume of LAW produced would affect the size and number of LAW disposal vaults built onsite.

Waste Blending

Each of the ex situ alternatives that would use vitrification as an immobilization technology assumed a waste blending factor of 1.2 for the HLW to account for variations in the composition of the waste during retrieval operations. Variations in the waste feed composition would not affect the calcined product that would be produced by the Ex Situ No Separations (Calcination) alternative. Uniform blending would require simultaneous retrieval from specific groups of tanks to deliver a uniform average feed stream to the treatment facilities. The blending factor would be multiplied by the volume of HLW produced under uniform blending conditions to calculate the waste volume expected due to variation in the waste feed. One of the major sources of uncertainty associated with developing a retrieval sequence that would achieve a uniform blending is the lack of accepted tank-by-tank inventory data. Preliminary studies on retrieval sequences, waste blending, and the effects on HLW volume show that the volume of vitrified HLW with no blending would be approximately twice that with total blending (WHC 1995p).

The volume of HLW produced combined with the size of the HLW canisters would directly impact the number of HLW packages requiring disposal at the potential geologic repository, which in turn would affect the cost associated with disposal. The number of HLW packages produced would also determine the number of offsite shipments required to transport the immobilized HLW to the potential geologic repository. The waste loading would also determine the concentration of radiological contaminants in the waste form. There is a relationship between the waste loading, number of shipments (cumulative probability of an accident), and the concentration of contaminants in the waste form (consequence of an accident). As the waste loading increased, the cumulative probability of an accident would decrease because there would be fewer trips required to transport the waste. The consequences of an accident would increase because there would be a higher concentration of contaminants in the waste form (see Volume Four, Section E.16.0 for a discussion of accident uncertainties).

Releases to the Soil During Retrieval

Retrieval operations under each ex situ alternative was assumed to result in the release of 15,000 L (4,000 gal) of waste at full solution strength from each SST to the surrounding soil. No leakage from the DSTs was assumed to occur during retrieval operations. This assumption was based on the 67 known or suspected SSTs that have leaked in the past (Hanlon 1995) and no known or suspected leaks from DSTs to date. Most of the SSTs were built in the 1940's and now are about 50 years old. The leakage volume estimate assumed that the average leakage from an SST would be one order of magnitude lower than the maximum release estimated for tank 241-C-106 during sluicing operations. The maximum leak estimated from tank 241-C-106 during sluicing operations was 150,000 L (40,000 gal). This estimate also assumed that the leak occurred early in the sluicing operation, leak detection devices and controls failed, sluicing operations proceeded without these leak detection devices, the leak(s) occurred at the bottom of the tank, and the remaining sludge did not plug any leaks (DOE 1995d).

The most probable occurrence of a leak during sluicing would involve the sluicers opening a plugged leak in the tank wall. The waste leakage during sluicing would be any free-standing liquid above the level of the leak point and the sluicing stream as it impacted the tank wall.

A nominal retrieval release inventory was developed by assuming that the waste would be diluted by one-third by adding water during waste retrieval. Possible dilution ratios that would be used during waste retrieval range from 3:1 to 10:1, depending on waste type. The nominal retrieval release inventory accounts for partial dilution of the tank contents while retrieval operations are underway. The volume of waste released during retrieval was assumed to be the same for the nominal and bounding cases. There currently is insufficient basis to support a lower nominal case leakage estimate. DOE currently is developing criteria and technologies to identify leaks and limit releases during retrieval.

Sensitivity Analysis

A sensitivity analysis was performed for the Ex Situ Intermediate Separations alternative to show the range in the data expected if the volume of HLW and LAW produced were to increase or decrease based on waste loading assumptions. The following sensitivity parameters were assumed for analysis:

- HLW loading at 15 weight percent and 40 weight percent waste oxides;
- LAW loading at 10 weight percent and 25 weight percent Na_2O; and
- No variation in the separations efficiencies or the blending factor.

The results of the sensitivity analysis performed for the Ex Situ Intermediate Separations alternative are shown in Table K.2.2.1. Lower waste loading would require increased resources, land commitments, transportation, and cost. The facility sizes were held constant for the sensitivity analysis, resulting in constant capital cost and staffing levels and variable operating schedules. If the treatment schedule were held constant, the required treatment facilities, capital cost, and staffing levels would change.

K.2.3 SCHEDULE

Schedules for construction, operation, and closure were developed for each of the alternatives within the constraints of the Tri-Party Agreement (Ecology et al. 1994). Schedule constraints would affect the size of the treatment facilities required to process the waste. Following design and construction of a waste treatment facility, the major schedule uncertainty would be the operating duration.

Each of the ex situ alternatives was developed using 60 percent overall operating efficiency, except for Phase 2 of Phased Implementation, which used 70 percent overall operating efficiency. Operating at higher efficiencies would reduce the operating duration, and conversely, lower operating efficiencies would increase the operating duration. For the alternatives that would have multiple treatment components, such as retrieval, pretreatment, HLW treatment, and LAW treatment, the overall operating schedule would depend on the operating efficiency for each component.

Uncertainties in the operating schedule would be expected to result in longer operating durations. Previous analysis has shown that the operating duration for the ex situ alternatives would be sensitive to the rate at which waste can be retrieved from the SSTs. A low SST sludge retrieval rate could increase the operating duration by 50 percent (WHC

1995r).

K.2.4 STAFFING

Staffing estimates were developed for each alternative in support of risk, accident, and socioeconomic impact analysis. These staffing estimates were developed using conservative assumptions for both construction and operating staffing levels. The major uncertainty in overall staffing requirements would be associated with the operating schedule uncertainty. Staffing requirements would be affected by operating efficiencies because operating efficiency changes would increase or decrease the operating duration and the overall staffing requirements.

Table K.2.2.1 Ex Situ Intermediate Separations Sensitivity Summary

K.2.5 RESOURCES

The resources required to construct and operate waste treatment facilities were estimated for each alternative using a consistent methodology and common assumptions. The ex situ alternatives and the In Situ Vitrification alternative would have the largest uncertainty for estimated resources. The major uncertainties associated with the estimated resource requirements for the ex situ alternatives include the size and type of facilities required and the volume of LAW and HLW produced. Variations in operating resource requirements as a function of waste loading for the Ex Situ Intermediate Separations alternative are shown in Table K.2.2.1.

K.2.6 COST

Cost uncertainty for all of the tank waste alternatives has been evaluated and is discussed in Volume 2, Section B.8. Upper and lower ranges were estimated for the major cost components of each alternative. Upper and lower cost ranges were based on the technology, level of development, and degree of complexity. These cost ranges along with confidence levels were used as input to Decision Science Corporation's Range Estimating Program for personal computers to model the treatment cost range and total cost range including repository fee.

The cost uncertainty results in a cost range within which the alternative cost would be expected to fall. The cost range is the highest for the In Situ Vitrification alternative at 3.3 percent below to 66.5 percent above the target cost based on the uncertainties associated with implementing this technology for remediation of the tank waste. Cost ranges for the ex situ alternatives are generally 3 to 8 percent below to 20 percent above the target cost. The Ex Situ Extensive Separations alternative results in an upper cost range of 35 percent above the target cost based on the application of many first-of-a-kind technologies and the complexity of the separations process.

K.3.0 UNCERTAINTY IN SOURCE TERMS

Source terms refer to the waste inventory, which is the total quantity of the hazardous material within the tanks, and to the release term, which is the amount released to environmental media such as soil, groundwater, surface water, and soil under normal or accident conditions. The following sections describe the uncertainty associated with inventory and release terms.

K.3.1 WASTE INVENTORY DATA

There is considerable uncertainty associated with the inventory data used in the EIS. Tank waste data are available on a tank-by-tank basis, but the accuracy of these data are suspect because they primarily are based on historical records of transfers between tanks rather than statistically based sampling and analyses programs. However, while the inventory of any specific tank may be suspect, the overall inventory for all of the tanks combined is considered more accurate. The lack of accepted tank-by-tank inventory data would affect the Ex Situ/In Situ Combination 1 and 2 alternatives more than other alternatives because the tank selection criteria and the impact assessment of waste disposed of in situ are dependent on tank-by-tank data.

The waste inventory data used in developing the alternatives and their associated impacts are derived from model predictions and sample analysis. While the waste is currently undergoing additional characterization and the inventory may be revised as a result of ongoing analyses, the inventory used in the EIS is not expected to result in discrimination for or against any of the alternatives analyzed. DOE has identified the key radionuclides for tracking in development of a "best basis inventory" for Hanford tank waste. These include the radionuclides that dominate the risk estimates in this EIS: C-14, I-129, neptunium-237 (Np-237), protactinium-231 (Pa-231), selenium-79 (Se-79), Tc-99, and uranium (U) isotopes. This information will be incorporated into National Environmental Policy Act (NEPA) analysis of closure alternatives. For additional information on tank inventory data accuracy and its effect on the EIS see Volume Two, Section A.3.

K.3.2 RELEASE TERMS

Releases to the environment for both routine releases during remediation and acute releases during an accident are a function of the waste inventory. The inventory used for developing routine emissions is based on a nominal waste stream based on overall tank waste inventory. Acute releases were developed using both a nominal and bounding inventory.

K.3.2.1 Chronic Releases (Routine)

Chronic releases were developed for each alternative using average inventory data. The No Action and Long-Term Management tank waste alternatives include routine emissions from the tank farms. The In Situ Fill and Cap alternative includes routine tank farm emissions as well as tank emissions during tank filling. The In Situ Vitrification alternative includes routine tank farm emissions plus releases from the evaporator and vitrification processes. The ex situ alternatives include routine tank farm emissions, releases during waste retrieval, and releases during waste treatment.

The routine releases developed for the ex situ alternatives are based on material balance calculations and waste processing rates. Conservative assumptions were made for the release of certain volatile radionuclides. It was assumed for each alternative that included vitrification that the entire inventory of I-129 and C-14 would be released to the atmosphere during waste treatment. Some capture of the I-129 in the off-gas treatment system could be expected and would result in lower I-129 releases.

Uncertainties associated with the chronic releases are based on the available inventory data. Increased inventory of any constituent would be expected to result in some increase in chronic releases. This especially would be true for the volatile contaminants.

K.3.2.2 Acute Releases (Accident)

The respirable fraction of inventory released from an accident, from which the receptor dose is calculated, is referred to as the source term. The source term depends on a variety of release fractions associated with the mechanics of the accident scenario. Uncertainties associated with each of these release fractions are based on available data, and in some cases may depend on engineering judgement. For specific scenarios, nominal and bounding values were estimated for the applicable release fractions as follows:

- Damage ratio (DR) - The fraction of the material at risk impacted by the event;
- Leak path factor (LPF) - The fraction that escapes the confinement boundary by design, natural causes, or degradation caused by the event;
- Airborne release fraction (ARF) - The fraction of released material made airborne by the event;
- Airborne release rate (ARR) - The fractional airborne release rate of material from the accident. ARR is converted to ARF by integrating over the time available for release; and
- Respirable fraction (RF) - The fraction of airborne droplets or particulate matter with individual particle aerodynamic equivalent diameter less than or equal to 10 microns (μm).

For the spray release scenario, the nominal and bounding applicable release fractions are presented in Table K.3.2.1. When a particular release fraction is well understood, the uncertainty diminishes, decreasing the difference between the bounding and nominal values. For purposes of this analysis, the DR is the only parameter with uncertainty. Setting LPF, ARF, and RF equal to 1.0 maintains conservatism even for the nominal case. The difference between the bounding and nominal cases is a factor of 7.

Table K.3.2.1 Bounding and Nominal Release Fractions Used in the Spray Release Scenario

K.4.0 UNCERTAINTY IN ENVIRONMENT TRANSPORT

The estimated movement of contaminants through environmental media such as soil, groundwater, surface water, and air is associated with uncertainties. These uncertainties are described in Sections K.4.1 through K.4.4, respectively.

K.4.1 TRANSPORT IN SOIL

This discussion on potential transport mechanisms is provided because 1) there may be other vadose zone transport mechanisms in effect in addition to what has been calculated; 2) there is insufficient information to determine whether any or all of the other transport mechanisms are active. The available data indicate that the primary vadose zone transport mechanism is advective flow through the interstitial spaces of the porous media. Recent observations of relatively immobile contaminants at depths of up to 38 m (125 ft) below the tanks are not fully explained with interstitial flow and may indicate there are other transport mechanisms in effect. These observations are currently the focus of a DOE program. The initial phase of the program is to determine if the observations are representative of extensive vadose zone contamination beneath the tanks or if they are related to other phenomena such as borehole contamination. The results from this program including subsequent phases are not expected to be available for several months.

All of the remedial alternatives would result in some waste tank release to the vadose zone. The impacts of these releases were predicted using the approach described in Volume One, Section 5.2.1. This approach required the mathematical definition of the waste tank releases (source terms), calculation of when and at what rate the release would move through the underlying vadose zone (vadose zone modeling), and calculation of when and at what rate the release would move through the underlying groundwater system and ultimately discharge to the Columbia River (groundwater models). A one-dimensional model capable of simulating partially saturated conditions was selected to calculate the transport of a waste tank release through the vadose zone to the underlying groundwater. The impact assessment of all the alternatives relied on a common conceptual model of the vadose zone, which included the geometry of each site (i.e., number and thickness of strata) where the releases would occur, the assumption that each strata was an isotropic and homogenous porous medium, that contaminant transport would be driven primarily by advection downward through the interstitial spaces of the various strata, that contaminant transport would be an isolinear process (i.e., independent of contaminant concentration), and that contaminant mobility as expressed by the distribution coefficient (K_d) parameter would remain constant in the various strata of the vadose zone. The conceptual model is the basis of the one-dimensional model used in the assessment approach.

Provided in the following subsections are discussions of 1) data on migration of past tank leaks in the vadose zone; 2) calculated transport of a past tank leak from tank 241-T-106 using the impact assessment assumptions; 3) potential vadose zone transport mechanisms other than what is inherently assumed in the impact assessment analyses; and 4) how the other potential vadose zone transport mechanisms could impact each alternative.

K.4.1.1 Past Tank Leaks

Sixty-seven of the 149 SSTs are assumed to leak (Hanlon 1995). The assumed leaking tanks are fairly evenly distributed in the 200 Areas with 32 assumed leaking tanks in the 200 East Area and 35 in the 200 West Area. There are no reported leaks from the 28 DSTs. The range of leak volume is from approximately 1,300 liters (L) (350 gallons [gal]) from tank 241-C-204 in the 200 East Area to 435,000 L (115,000 gal) from tank 241-T-106 in the 200 West Area. Total leak volume from all 67 assumed leakers ranges from 2.27E+06 to 3.41E+06 L (600,000 to 900,000 gal). Interim stabilization has been completed on all but five assumed leaking tanks. The tank identification number, date the tank was declared a leaker, estimated leak volume, estimated activity of leak, and date the tank was stabilized are provided in Table K.4.1.1.

Cesium (Cs) and plutonium (Pu) were transported to the tank farms in various waste streams. Both contaminants are relatively immobile in subsurface materials at Hanford and because of this immobility, are expected to be found near waste disposal sites (especially under ambient infiltration conditions) dispersed throughout the unsaturated materials and in groundwater in some instances, depending on the volume of liquid associated with the waste discharge or leak.

Information has been emerging that associates migration of several radioisotopes, including Cs and Pu, to depths of 30 m (100 ft) or greater with leaks from the waste tanks. There are two major sources of this data as follows:

- Downhole logging of existing drywells; and
- Discrete samples from a borehole completed in multiple stages to avoid cross contamination.

Downhole Logging of Drywells

DOE has a system of monitoring wells called drywells installed in the vicinity of each waste tank. The depth of these drywells varies, but they do not extend to the water table of the unconfined aquifer.

Table K.4.1.1 Summary of Tank Leak Estimates from Single-Shell Tanks

These drywells were installed as a way of detecting gamma emissions and serve as an indirect means of detecting or confirming waste tank leaks and mobilization of existing contamination in the vadose zone by other waste sources such a potable water line leaks. Until recently, the gamma emissions that were detected were indicative of undifferentiated radioisotopes. Such emissions have been detected in many of the drywells at depths ranging from ground surface to depths up to 38 m (125 ft) belowground surface. Recent improvements in the borehole logging detection equipment has resulted in the identification of specific gamma-emitting radioisotopes. Thus, previously characterized gross gamma contamination is now specifically linked to several radioisotopes. The most prevalent radioisotope detected was Cs-137, while other gamma-emitting radionuclides such as cobalt-60 (Co-60), europium-152 (Eu-152), and Eu-154 were generally found near the surface and are believed to be the result of spills (Brodeur 1996).

The improved geophysical logging uses a spectral gamma logging system (SGLS) with high-purity intrinsic germanium detection device to provide assays of gamma-emitting radionuclides near the drywells. The approach, data, and interpretation are provided in Brodeur 1995. Application of the improved logging equipment has resulted in additional information on conditions at the SX Tank Farm. Application of the improved logging equipment has resulted in additional information on conditions at the SX Tank Farm.

Ten of the 15 tanks in the SX Tank Farm are assumed or verified as leaking. Tanks in the SX Tank Farm have been verified as leaking as early as 1962 (Table K.4.1.1). The last reported tank to leak in the SX Tank Farm was in 1988. Cumulative estimated leak volume from this tank farm ranges from 5.02E+05 L (132,000 gal) to 6.31E+05 L (167,000 gal) as shown in Table K.4.1.1. Ninety-five drywells ranging in depth from 23 m (75 ft) to 38 m (125 ft) from ground surface were logged with the SGLS in the SX Tank Farm. The most abundant and highest-concentration radionuclide detected was Cs-137, which was detected in virtually every borehole (Brodeur 1995). The Cs-137 was detected at the following depths in several drywells: 23 m (75 ft) in drywells 41-09-03 and 41-08-07; 32 m (105 ft) in 41-09-04; 27 m (90 ft) in 41-11-10, and 38 m (125 ft) in 41-12-02.

Other human-made gamma-emitting radionuclides detected include Co-60, Eu-152, and Eu-154, which generally were found near the surface and are believed to be the result of spills (Brodeur 1995). The Co-60 was found in drywell 41-14-06 only and was detected a depth of 17 m (55 ft) to 23 m (76 ft) below ground surface.

The transport of Cs-137 in the vadose zone sediments at the Hanford Site is believed to be greatly retarded due to adsorption. The Cs would not be expected to be found at depths of up to 38 m (125 ft) if it were being transported via interstitial flow through the sediment pore spaces and under ambient conditions that include neutral pH and infiltration rates ranging from 2 millimeters (mm)/year to 10 centimeters (cm)/year. The detection of Cs-137 at this depth raises several questions concerning the active transport mechanisms. These questions and others are being addressed by DOE in a Resource Conservation and Recovery Act Groundwater Assessment of the S and SX Tank Farms (Caggiano et al. 1996) has recently been implemented. The improved borehole logging detection equipment provides information on the specific contaminant in the vicinity of the drywells, but there is still uncertainty on the lateral distribution of these contaminants within the vadose zone.

Borehole Samples from Multiple-Stage Well

The borehole sample data were collected as a part of a 1993 investigation (Freeman-Pollard 1994) of contaminant migration from a leak from tank 241-T-106. The data from the 1993 investigation consist of 43 split-spoon samples from borehole 299-W10-196. These samples were taken for physical, chemical, and radiochemical analysis in addition to spectral gamma geophysical logging of the borehole on eight occasions.

The 1993 subsurface investigation of the tank 241-T-106 leak was the third to be performed since the initial leak was discovered in 1973. The first investigation was conducted from June to August 1973 in which 16 single-cased boreholes were drilled, the deepest to approximately 27 m (88 ft) below ground surface, as summarized in the 1993 investigation report (Freeman-Pollard 1994). Samples were collected at 1.5-m (5-ft) intervals as the boring was advanced. From this investigation, it was concluded that contamination penetrated to a maximum depth of about 27 m (88 ft).

Freeman-Pollard indicates that in 1979, a second investigation was completed based on numerous additional single-cased boreholes drilled between 1973 and 1978 (Freeman-Pollard 1994). One of the conclusions of this investigation was that there was no evidence that contaminants from the tank 241-T-106 leak had reached the underlying aquifer nor would it during the "hazardous lifetime" of the radionuclides. The 1993 investigation resulted in data on the vertical distribution of several radionuclides and chemicals. Most notably are the following results.

- The Pu concentrations increased greatly at the depth of the bottom of the tank 11 m (36 ft) below ground surface, reached a peak at 13 m (43 ft), decreased to less than 1 pCi/g at 28 m (92 ft), spiked at 29 m (95 ft), and then decreased to background at greater depths.
- The Cs-137 was the only radionuclide that had a high concentration within the fill around the tanks to a depth of 4 m (13 ft) below ground surface, above the presumed depth of the tank leak. The concentration decreased to a depth of 9 m (30 ft), then began to increase to a maximum at 14 m (46 ft), followed by a decrease to below background until two spikes were detected at 24 m (78 ft) and 30 m (100 ft).
- The spikes at approximately 30 m (100 ft) are observed for both mobile (e.g., Tc-99) and attenuated (e.g., Cs-137) contaminants and may be concentrated by a caliche layer that occurs at this depth. This may be due to a hydraulic conductivity contrast, adsorptive capacity from the increased clay content, and/or substitution of radionuclides in the calcium carbonate.

From the 1993 investigation, it was concluded that the mobile contaminants in the leading edge of the plume such as Tc-99 from the 1973 leak had penetrated to the contact with the Ringold unit E at 37 m (121 ft) below ground surface (Freeman-Pollard 1994). This represents a distance of 26 m (85 ft) over approximately 10 years. There was a spatial distribution of radioisotopes in the vadose zone that reflected the differences in their mobility (Freeman-Pollard 1994). At shallow depths, 10 to 24 m (33 to 82 ft), the less mobile or relatively immobile contaminants Cs-137, americium-241 (Am-241), Pu-239/240, Eu-154, strontium-90 (Sr-90), and C-14 were found. Carbon is assumed to be a mobile (K_d = 0) contaminant in Hanford Site sediments, thus its inclusion here is unclear.

K.4.1.2 Transport of Mobile Contaminants Associated with Past Tank Leaks

As stated previously, the groundwater impact assessments all are based on the assumption that contaminant transport occurs as the downward advection of water through the interstitial pores spaces of the various strata. It is difficult to provide an intuitive comparison between contaminant distribution from past leaks and contaminant distributions in the vadose zone calculated for the Tank Waste Remediation System (TWRS) alternatives because the volumes and rate of volume released from the TWRS alternatives generally would be much lower than the past tank leaks, specifically, the leak from tank 241-T-106. The leak from tank 241-T-106 was estimated to be approximately 435,000 L (115,000 gal) over a 52-day period. Contaminants from this leak have been identified in the vadose zone at depths of up to 30 m (100 ft) below ground surface. Scoping calculations consisting of two vadose zone simulations of the tank 241-T-106 leak were performed using the major assumptions used for the impact assessment described in Volume Four, Appendix F to provide a comparison of predicted contaminant distribution from the leak to observed contaminant distribution. A brief description of the simulations and the results follow.

The vadose zone model (VAM2D) was used to perform two axi-symmetric simulations of the vadose zone transport of contaminants due to a leak from tank 241-T-106. The upper boundary of the model was taken as the bottom elevation of the tank. The model domain extended a distance of 52 m (170 ft) from the upper boundary to the water table. Strata thicknesses and properties were the same as assumed for source area 1WSS for the impacts assessments in Volume Four, Appendix F. The axis of symmetry is the centerline of the tank, which has a radius of 11 m (37 ft). For both simulations, the flow field is first equilibrated to steady-state conditions, assuming no flow from the lateral boundaries, a zero pressure head along the bottom boundary, which represents water table conditions, and a spatially varying infiltration rate along the surface domain. The infiltration rate is zero for the domain from the centerline to 11 m (37 ft) radially to represent the umbrella effect of the tank. From 11 m (37 ft) to 111 m (365 ft), infiltration is 10 centimeters (cm)/year (4 inches [in.]/year) to represent enhanced infiltration due to the gravel surface around the tank. From 111 m (365 ft) to 161 m (530 ft), the infiltration rate drops linearly from 10 cm/year to 2 millimeters (mm)/year (4 to 0.08 in./year). Beyond 161 m (530 ft) to 1,500 m (4,900 ft), the infiltration rate is 2 mm/year (0.08 in./year), representing ambient conditions on relatively undisturbed land.

Both simulations assumed the leak to be 435,000 L (115,000 gal) over a 52-day period infiltrating into an area of 10 square meters (m^2) (1,000 square feet [ft^2]) at the centerline of the tank. The first simulation assumed the leak as described is superimposed on the infiltration scenario (no infiltration under the tank). The second simulation assumed that there would be an infiltration rate of 10 cm/year (4 in./year) over the domain from the tank centerline to 11 m (37 ft). Beyond this distance, the infiltration rate was assumed to be the same as described above. Table K.4.1.2 summarizes the calculated travel distance and elapsed time for the contaminant front from the tank 241-T-106 leak. This is for a mobile contaminant (K_d = 0) and the major assumptions used for the impact assessment.

Table K.4.1.2 Calculated Transport Distance and Time Based on Leak from Tank 241-T-106 for a Mobile Contaminant

For a mobile contaminant such as Tc-99, the above described simulations agree with the observation from the 1993 investigation of the tank 241-T-106 leak (Freeman-Pollard 1994) where it was found that Tc-99 had penetrated 37 m (120 ft) below ground surface. The 1993 investigation also indicates that normally much less mobile contaminants such as Cs-137 and Pu were found at nominal depths of 30 m (100 ft). This could be the result of an additional transport mechanism(s). Several potential transport mechanisms could be contributing to the transport of Cs-137 and Pu to depths of 30 m (100 ft). DOE currently has undertaken an investigation that should provide the information needed to ascertain if other transport mechanisms such as preferential flow paths and/or chemically enhanced mobility of selection contaminants are active.

K.4.1.3 Potential Vadose Zone Transport Mechanisms

In this section, potential vadose zone transport mechanisms are identified. The potential vadose zone transport mechanisms are divided into two categories: transport mechanisms controlled by physical processes and transport mechanisms controlled by chemical processes. Included in this discussion are occurrences or phenomena that could enhance or speed up contaminant transport in the vadose zone.

K.4.1.3.1 Potential Physical Vadose Zone Transport Mechanisms

Physical transport mechanisms can be either natural or human-made. Potential physical transport mechanisms and transport enhancing phenomena that could occur at the tanks include the following:

- Advective flow through clastic dikes and clastic sills that might naturally occur beneath and/or near the tank farms;
- Advective flow through breaks in the caliche layer (where it occurs) in the Plio-Pleistocene unit of the Ringold Formation that might naturally occur beneath and/or near the tank farms;
- Advective flow through the unsealed annular space surrounding the well casing and borehole in drywells/monitoring wells installed near the tanks;
- Infiltration of surface runoff into the unsealed annular space between the well casing and borehole in

drywells/monitoring wells installed near the tanks;
- Inflow of surface water into the top of drywells and discharge out through casing perforations at depth;
- Movement of contamination during drilling from near-surface sources to various depths; and
- Near surface leaks from water lines and/or waste transfer lines.

Each of the identified potential physical transport mechanisms listed are illustrated conceptually in Figure K.4.1.1. In the following paragraphs, a description of the potential transport mechanisms is provided.

Advective Flow Through Clastic Dike and Clastic Sills

Clastic dikes are ubiquitous in the 200 Areas and have been observed in the excavation of most major facilities in the 200 Areas including processing facilities and waste tanks (Fecht-Weekes 1996). Clastic dikes are lenses or tabular bodies, relatively narrow 18 to 38 cm (7 to 15 in.) (Fecht-Weekes 1996), with textural characteristics similar to the host sediment (clay and sand). Clastic dikes occur as near-vertical sediment-filled structures that cut across bedding planes of the Hanford Formation. Clastic sills are tabular structures of sedimentary material similar to clastic dikes but they are oriented parallel to the plane of the surrounding sediments. Figure K.4.1.1 depicts a conceptual cross section under a tank farm and includes an illustration of what a clastic dike and clastic sill would look like if exposed in an excavation. Clastic dikes have been observed to form polygons, based on observations of the Environmental Restoration Disposal Facility (ERDF) excavation (Fecht-Weekes 1996). A multisided polygonal cell encloses the host sediments. Individual polygonal cells are bounded by other polygons to form what is described as a honeycomb pattern when viewed from the air. The genesis of clastic dikes in not certain. There are several theories but the evidence is limited and does not conclusively support one theory. As with the genesis of clastic dikes, little is known about their hydraulic characteristics. Some inferences can be made from material descriptions where they have been intercepted by excavations and the lack of discernable impacts to groundwater levels and quality. The margins or vertical boundaries of clastic dikes are characterized by "clay skins," which are thin silt laminae that vary in thickness from 0.2 to 1 cm (0.08 to 0.4 in.). Internally, the dikes are composed of unconsolidated sedimentary infilling that trend parallel to the dike walls (Fecht-Weekes 1996).

The degree to which clastic dikes would function as a conduit (preferential flow path) or barrier to flow would depend on the relative amounts of clay and sand in the clastic dike and the continuity of any sand stringers within the clastic dike. Based on the observations of clastic dikes in excavations on the 200 Areas Plateau, the inferred hydraulic nature of the dikes is that of potentially a minor barrier to flow perpendicular to the dike. The clay content and lack of sand stringer continuity suggests that clastic dikes do not function as preferential flow paths for vertical flow.

Figure K.4.1.1 Conceptualization of Potential Vadose Zone Contaminant Transport Mechanisms

Advective Flow Through Breaks in the Caliche Layer in the Plio-Pleistocene Unit

Caliche layers generally would be a barrier to downward migration of contaminants in the vadose zone, if the layers were sufficiently extensive. Caliche layers were not included as discrete layers in the vadose zone modeling of contaminant transport. The Plio-Pleistocene unit, in which caliche layers generally are found, was included in the modeling assessment for source areas in the 200 West Area, and appropriate average material properties for this unit were used (Wood et al. 1995).

The presence of an intact, laterally extensive caliche layer would promote lateral spreading of infiltrating water. As a potential transport mechanism, breaks in the caliche layer in the Plio-Pleistocene unit would result in less lateral spreading and could allow for faster downward contaminant transport. Such breaks would function as a preferential flow path but only over a relatively short vertical distance. The overall thickness of the Plio-Pleistocene unit assumed for the vadose zone modeling assessments varies from approximately 4 to 5 m (13 to 16 ft) and caliche layers within this unit would be expected to be from 0 to 1 m (0 to 3 ft) thick.

Advective Flow Through the Unsealed Annular Space in Drywells and Groundwater Monitoring Wells

The unsealed annular space between the well casing and borehole in drywells affords the potential for 1) mobilizing contaminants that may be located at various elevations adjacent to the drywell; and 2) providing an additional driving force that could mobilize contaminants from past tank leaks that have migrated deeper into the vadose zone but not necessarily adjacent to the drywell.

Drywells and older groundwater monitoring wells have been installed near each tank for environmental monitoring and were drilled through near-surface contamination from tank leaks and other releases. These wells all were constructed with a cable tool drilling method in which the steel casing was driven down as the bottom of the borehole was cleaned out with the cable tool. A hardened steel drive shoe with a outside diameter larger than the casing diameter (diameters vary with driller and with available materials) by approximately 1.3 cm (0.5 in.) was attached to the bottom of the casing as it was being driven down the borehole. The annular space between the casing and borehole was not sealed. In the drywells, perforations in the steel casings have been made at various depths. The groundwater monitoring wells were installed with a screened section at the bottom that typically extended from 3 m (10 ft) above the water table to 6 m (20 ft) below the water table.

Drywells are similar to the older groundwater monitoring wells (Figure K.4.1.1) in the tank farm area except that drywells do not extend to the groundwater table and perforations in the drywells were made at various elevations. Drywells were installed to allow for periodic monitoring of radioactivity in the vadose zone from ground surface to the depth of the drywell. Increases in radioactivity detected in the drywells were indicative of a tank leak or migration of existing radioactivity in the vadose zone in response to another water source such as a leaking water line.

The hydraulic characteristics of the annular space between the well casing and borehole are not known. Because this space was not sealed and a drive shoe with larger outside diameter than the casing was used, there exists the potential of voids and loosely packed sand and gravel that potentially could function as a preferential flow path for contaminant migration vertically through the vadose zone.

Infiltration of Surface Runoff into the Unsealed Annular Space of Drywells/Monitoring Wells

Infiltration of surface water or other near-surface liquid sources such as from a leaking water line (Figure K.4.1.1) has the potential for 1) mobilizing the near-surface contamination through which some of the wells were drilled; and 2) providing an additional driving force that could mobilize contaminants from past tank leaks that have migrated deeper into the vadose zone.

Large volumes of water, such as flooding of drywells, have been known to occur at some of the tank farms and water line leaks have been extensive enough to cause surface subsidence. Water sources such as described, combined with potential preferential flow paths created by unsealed annular spaces of drywells and monitoring wells could result in the mobilization of near-surface contaminants to greater depths within the vadose zone. Contaminants such as Cs-137, which are immobile in Hanford-type sediments under ambient conditions, would be expected to travel down the annular space with the saturation front and remain relatively close to the drywell. Mobile contaminants such as Tc-99 also would travel down the annular space with the saturation front but would be able to move farther laterally than less mobile contaminants, especially if lower conductivity units such as a caliche layer were encountered, which would promote lateral spreading. This potential phenomena is illustrated in Figure K.4.1.1.

The potential mobilization of near-surface contaminants as described also could apply to contaminants that are deeper in the vadose zone such as might occur from a past tank leak. The Cs is not expected to migrate far from the tank under ambient conditions and advective flow through the interstitial pore spaces of the sediments. Thus, a Cs plume from a past tank leak would have to intercept the annular space near the leak for Cs-137 to be mobilized and transported deeper in the vadose zone via the potential annular space pathway (Figure K.4.1.1).

Inflow of Surface Water into the Top of Drywells

This potential transport mechanism entails pipe flow down the inside of the drywell casings. The construction of drywells is discussed previously. Inflow of surface water into the drywell casings has the potential of mobilizing the deep-seated contaminants from past tank leaks or other sources by providing an addition driving force.

As discussed, large volumes of water such as flooding of drywells, which has been known to occur at some of the tank farms potentially could enter drywell casings. If sufficient water from sources such as this enter the drywell casings, they would flow out of casing perforations and/or the bottom the casing if unsealed. This could result in the mobilization of deep-seated contaminants. This potential transport mechanism would not affect contaminants such as Cs-137, which are immobile in Hanford-type sediments under ambient conditions unless there are casing perforations near the elevation of the bottom of the tank leak and/or the Cs-137 was transported to a greater depth via a transport mechanism such as one involving a preferential flow path or chemically enhanced movement.

Movement of Contamination During Drilling

This potential transport mechanism involves the physical movement of particles during the drilling process from a higher elevation to a lower elevation. Many of the drywells were drilled through near-surface contamination. In addition, the drilling was not staged to prevent cross-contamination, the annular space between the single casing and the borehole was not sealed, and the cable tool drilling method potentially could carry near-surface contaminants to a greater depth. The impact on the underlying groundwater would be expected to be insignificant. Such occurrences could complicate data analyses or cause misinterpretation of data collected from the drywell monitoring programs.

Near-Surface Leaks from Water Lines And/Or Waste Transfer Lines

Even in the absence of potential preferential flow paths such as the annular space between well casings and boreholes or clastic dikes, large volumes of water such as from water line leaks, construction activities, or surface flooding could provide a driving force to quicken the transport of contaminants at all elevations.

K.4.1.3.2 Potential Chemical Vadose Zone Transport Mechanisms

As discussed in the introduction to this section, potential chemical-related transport mechanisms are the least understood of all the transport mechanisms especially considering the extremely high pH liquors present in the waste tanks. However, as will be discussed in the following paragraphs, chemical-related transport mechanism(s) may be responsible in part for the observation of contaminants such as Cs-137 at 38 m (125 ft) below the SX Tank Farm, which is deeper in the vadose zone than would have been expected based on the present understanding of the leak volume and contaminant mobility in the near-tank environment.

Potential chemical transport mechanisms may be associated with 1) sodium (Na) from the waste tanks and its effect on the mobility of some contaminants; 2) the reaction of hydroxide in the waste tanks with minerals in the vadose zone resulting in greater mobility of otherwise relatively immobile contaminants; and 3) the reaction of complexing agents that may be in the waste tanks with otherwise relatively immobile contaminants such as Co-60 and Sr-90 causing them to be more mobile. Potential chemical transport enhancing phenomena that could be in effect at the tanks include enhanced mobility resulting from; Na exchange, dissolution, and formation.

Enhanced Mobility Resulting from Sodium Exchange

Many of the defense mission processes involved acid dissolution. The resulting waste was neutralized with sodium hydroxide before being routed to the waste tanks. This practice has resulted in the presence of Na in the tank wastes at high concentrations and high pH (e.g., pH 12). As a consequence, Na may exchange for naturally occurring divalent cations such as calcium (Ca) and magnesium in the soil column. At high pH values, such as would occur when the tank contents had first exited the tanks, the surfaces of the mineral particles would be negatively charged and would attract cations. The presence of high Na concentrations near these mineral surfaces could cause the desorption of other ions from the mineral surfaces as shown in the following equation modified from Caggiano 1996:

mNa^{+} (bulk solution) + nCa^{++} (mineral surface double-layer) =
xNa^{+} (mineral surface double-layer) + yCa^{++} (bulk solution)

This exchange process could result in more divalent cations reaching the groundwater and less Na than expected. This is consistent with observations and groundwater quality analyses from a well downgradient of the S and SX Tank Farms. An important consequence is that, under high Na conditions, Sr-90, which is chemically similar to Ca, may likewise be mobilized and migrate to a greater extent than previously expected. Other waste tank constituents may be affected similarly.

Enhanced Mobility Resulting from Silicate Mineral Dissolution

The neutralization of the wastes with sodium hydroxide meant that the tank contents were high pH, sometimes approaching a pH of 12. Many studies have shown that dissolution of silicate minerals such as those in the underlying vadose zone sediments would be accelerated at high pH and high temperature (Caggiano 1996). The dissolution reactions would occur when leaks from the tanks, some of which were self-boiling, contacted the mineral particles in the vadose zone. Such dissolution processes potentially could result in gelatinous reaction products that could cover the mineral exchange sites, which would enhance the mobility of contaminants such as Cs-137 that normally are retarded by exchange. However, the gelatinous reaction products could have the opposite effect by impeding moisture migration through the soil. This potentially could cause the soil permeability to be lower than that of the unaltered material, resulting in slower contaminant movement.

Another possible effect of silicate mineral dissolution is the leaching of previously adsorbed Cs-137. If the surface of silicate minerals in the vadose zone was dissolved, micro- and macropores could be opened. This in turn could lead to the leaching of Cs-137 that previously had been adsorbed. Heat from the tanks and the heat of leaking waste could increase the rate of silicate mineral dissolution and increase the Cs-137 release rate.

Enhanced Mobility Resulting from Complex Formation

Metal-organic complexes are compounds with a cyclic structure in which the organic components are bonded to the central metal ion. Millions of pounds of complex-forming organic chemicals such as citrate, glycolate and ethylenediaminetetraacetic acid (EDTA) were used for the recovery of U and Sr and subsequently discharged to the tanks. Once in the tanks, it would be possible for these complex-forming chemicals to react with other cationic constituents of the tank waste. Not all contaminants will react with organic complexing agents such as EDTA; generally, this interaction does not take place with monovalent cations such as Na, potassium, or Cs (Hill 1992). The Cs has very little potential for complexing with the organic chemicals found in the waste tanks. Complexing reactions may take place with other cations including the actinides and lanthanides. While it is known that metal-organic complexes will remain in solution under conditions where the metal ion itself would precipitate, there is a lack of data on the mobility of these complexes. Presumably, the complex would move relatively further and faster than the ion, but K_d values for metal-organic complexes remain a subject for future study and investigation. Also, the ability of the complexing agents to remain active in the presence of high temperature and ionizing radiation is uncertain.

K.4.1.4 Potential Impact on TWRS Alternatives

Most of the potential vadose zone transport mechanisms, if active, would result in earlier contaminant first arrival at the vadose zone/groundwater interface, earlier peak concentrations, and higher peak concentrations for some or all of the contaminants, depending on the mechanisms. The following provides a qualitative description of the potential impact of the vadose zone transport mechanisms on each alternative and mitigation measures where applicable.

Preferential flow through clastic dikes and sills would result in earlier contaminant first arrival and peak times and higher peak concentrations in groundwater for all alternatives and contaminants and would be difficult to mitigate directly. The dikes first would have to be located with methods that possibly could include surface geophysics and test pits. Then, a sealing material that would withstand the chemicals in the tank waste would have to be injected effectively into the structure. Alternatively, a grout barrier could be considered. Overall, it may be unlikely that clastic dikes and sills could be directly mitigated. For ex situ alternatives, an effective indirect mitigation would be to reduce retrieval loss volume and contaminant concentrations.

Flow through breaks in a caliche layer is not expected to impact any of the alternatives because "credit" was not taken for caliche layer attenuation in the impacts analyses. Flow through drywell annular space from TWRS releases would have an effect on the No Action and Long-Term Management tank waste alternatives similar to that described for clastic dikes and sills. Mitigating the effect of flow through drywells would be relatively easily accomplished with a drywell removal (plugging) and/or drywell rehabilitation program. The other in situ and ex situ alternatives presumably would not be impacted because the drywells would be removed and plugged prior to installation of a cap over the tank farms.

Inflow of surface water into the drywell casings and annular space could decrease vadose zone contaminant transport time for the No Action and Long-Term Management alternatives. The effect on peak concentrations is uncertain. Peak concentrations could be reduced due to the dilution effect of surface water in flow. Mitigation such as plugging could be performed as described previously. The other in situ and ex situ alternatives would presumably not be affected because the drywells would be removed prior to installation of a cap over the tank farms. Cross contamination during drywell construction would not have an impact on any of the TWRS alternatives. Near-surface leaks from potable waste and waste water could decrease vadose zone contaminant transport time for the No Action and Long-Term Management alternatives. Mitigation would be relatively easy and would involve the removal of all utility lines from the tank farms area. The other in situ and ex situ alternatives would not be impacted because the utility lines would be removed prior to installation of a cap over the tank farms.

The three identified chemical transport mechanisms would result in earlier contaminant first arrival at the vadose zone/groundwater interface, earlier peak concentrations, and higher peak concentrations for some of the otherwise relatively immobile contaminants for all of the alternatives except the In Situ Vitrification alternative. The potential effects of the Na exchange and sediment dissolution transport mechanisms could be limited to near-tank due to the dilution of Na and hydroxide with natural water and would be rendered totally inactive at the saturated water located at 65 to 85 m (210 ft to 270 ft) below ground surface. The potential effect of enhanced mobility from complexing agents and the extent into the vadose zone and groundwater remain a subject for future study and investigation.

Depending on the resolution of the transport mechanisms that are currently active, it might or might not be necessary to take additional measures to control leaks during retrieval and remediate contaminants in the soil during tank farm closure.

It is not known if any of the potential transport mechanisms are active. Further, the potential transport mechanisms involving chemical enhancement are poorly understood. Mitigation of the chemical-related transport mechanisms could include indirect approaches such as reducing the volume and concentration of contaminants released during retrieval. Direct mitigation may be effective but much more information is needed about this type of potential transport mechanism.

K.4.2 TRANSPORT IN GROUNDWATER

The analyses of potential impacts on groundwater required several assumptions to address uncertainties. The major assumptions and uncertainties either are related to natural variables (e.g., vadose zone and aquifer parameter values) or are inherent to the assessment approach. Modeling assumptions are described in Section 4.2.1.

Post-remediation health risks to the public from TWRS alternatives would result from contaminants in the groundwater. The first arrival of any contaminant at the interface between the vadose zone and groundwater would occur between 140 and 250 years following remediation with the Long-Term Management and No Action alternatives. The tank inventory would be released faster for these alternatives than for any of the other alternatives, because it is assumed that there would be no engineered barriers to reduce infiltration or any attempt to remove or stabilize the tank waste. The first arrival of contaminants from the other alternatives would occur at about 2,000 years and the peak concentrations at about 5,000 years in the future.

Cumulative radionuclide concentrations that could occur in the groundwater from a potential combination of contamination from past disposal practices, currently anticipated future waste disposal, and the contamination from the TWRS alternatives are discussed in Volume Four, Appendix F.4.5. Peak groundwater concentrations from the various potential sources may occur at different times and different locations. However, to maximize the potential cumulative impacts, the peak concentrations of the past and reasonably foreseeable future sources were assumed to combine with the peak concentrations from the TWRS alternatives. This results in a conservative bounding of the maximum potential cumulative groundwater impact for each TWRS alternative. A more detailed modeling of the potential cumulative impacts will be done in a future Hanford Site EIS. The results of the future analysis likely would indicate lower cumulative groundwater impacts than presented in this bounding analysis.

The highest cumulative groundwater concentrations occur for the No Action and Long-Term Management alternatives. The tank waste is the dominant contributor to the predicted concentrations. The other alternatives result in much lower cumulative radionuclide concentrations, and the dominant contributor is contamination from past disposal practices. The radiation dose and risk to the potential future user of the contaminated groundwater, the time at which it could occur, and the percent attributable to TWRS waste for each alternative are presented in Volume One, Table 5.13.5. The table is based on a hypothetical onsite farmer who is assumed to use the groundwater at the maximum cumulative point of concentration for each alternative. The groundwater is assumed to be used for all purposes, including drinking, washing, and gardening for 30 years. Future solid waste disposal at the 200 West Area solid waste burial ground and the ERDF collectively would contribute about 5 rem of the hypothetical 30-year resident farmer dose presented. Less than 10 mrem of the hypothetical 30-year resident farmer dose would be attributed to past and future solid waste disposal at the US Ecology solid waste burial ground.

K.4.2.1 Modeling Assumptions

Volume Four, Appendix F provides the basis of the groundwater impact analysis for the TWRS alternatives. The groundwater assessments in Volume Four, Appendix F required several assumptions to address uncertainties in some of the data. The major assumptions and uncertainties are related to either the natural system (i.e., an understanding and ability to assign vadose zone and aquifer parameter values) or uncertainties inherent to the assessment approach.

The most important assumptions and uncertainties are as follows:

- The rates of infiltration into natural ground and through a cap;
- Distribution coefficient (K_d) of contaminants;
- Uncertainty in future groundwater flow direction due to decay of groundwater mounds onsite and future land-use changes;
- Uncertainty in future groundwater flow direction and vadose zone thickness due to climate change;
- Uncertainty in vadose zone transport due to use of one-dimensional flow and transport simulation; and
- Uncertainty due to calculation of releases during retrieval.

Infiltration

Infiltration is one of the key driving forces for contaminant movement through the vadose zone. It affects the time of contaminant transport through the vadose zone: a higher rate results in a faster flow rate within the vadose zone and a shorter contaminant transport time.

Infiltration varies temporally and spatially. The temporal variation occurs seasonally with changes in temperature, plant activity, and precipitation and over longer periods as a result of climatic change. The spatial variation occurs with changes in vegetation type, surficial soil type, and human-made structures, such as paved parking lots. The vadose zone flow field varies temporally and spatially in response to infiltration rate changes. However, it is not directly measurable with conventional techniques and is modeled based on vadose zone parameters and the assumed infiltration rate. There is also a lag time between a change in infiltration rate at the surface and a change in the flow field in the vadose zone as the water percolates into the ground.

For each alternative, the initial infiltration rate (i.e., the rate before implementing remediation or no action) is assumed to be 5 cm/year (2 in./year). This rate is within the range of reported values for the Hanford Site and is appropriate given 1) the recent ground cover changes in the tanks vicinity; 2) the uncertainties in future ground cover conditions; and 3) the one-dimensional vadose zone flow and transport model used for the simulations. Infiltration in the 200 Areas is reported to range from near zero, where the ground cover is a shrub-steppe type characteristic of predevelopment conditions, to 10 to 13 cm/year (4 to 5 in./year), where the ground is unvegetated sand and gravel, characteristic of conditions around the tank farms since the mid-1940's or later (Gee et al. 1992). For alternatives that incorporate a cap, limited sensitivity analysis has shown that the contaminant transport through the vadose zone is not sensitive to the initial infiltration rate (Volume One, Section 4.3.5).

The higher infiltration in the vicinity of the tanks is a relatively recent occurrence in response to ground cover modifications in the last 50 years. These modifications are not expected to have changed the flow field at depth within the vadose zone from that of predevelopment conditions. For alternatives involving a cap, conditions after the cap is installed are assumed to be representative of predevelopment conditions in that the infiltration in the tank vicinity would be low. Infiltration is assumed to remain at 5 cm/year (2 in./year) for the No Action and Long-Term Management alternatives.

Spatially, the rate would be expected to be lower away from the tanks where vegetation is present and surficial soils are of a finer texture. The one-dimensional model used for contaminant transport simulations through the vadose zone does not account for these infiltration changes with time and space. Thus, the assumed infiltration rate of 5 cm/year (2 in./year) was chosen as a conservative estimate.

The No Action and Long-Term Management alternatives are the only two tank waste alternatives that would not involve placement of a cap over the tanks. If a higher infiltration rate was assumed (i.e., greater than 5 cm/year [2 in./year]), the result would be earlier contaminant arrival in the groundwater with higher peak concentrations. Conversely, use of a lower infiltration rate would result in a delayed effect with somewhat lower peak contaminant concentrations.

Distribution Coefficients

The various contaminants in the tank waste each have their own chemical characteristics and would interact with the groundwater and geologic materials differently. An indication of a contaminants mobility in the vadose zone and groundwater aquifer is the distribution coefficient (K_d). A contaminant moves with the speed of water if its K_d is zero and progressively slower than water as the K_d value increases. This difference would result in different rates of contaminant movement in the vadose zone and groundwater, ranging from that of groundwater to no measurable movement over a period of hundreds of years.

The tanks contain more than 100 radioactive and nonradioactive contaminants that potentially would impact groundwater. Contaminants that are insoluble were assumed not to leach to groundwater. The K_d values for the contaminants range from zero (in which the contaminant's movement in water is not retarded) to more than 100 (in which the contaminant moves much more slowly than water). Therefore, the contaminants were grouped as follows based on their mobility in the vadose zone and underlying unconfined aquifer:

- Group 1 - Nonsorbing (K_d = 0); K_d values in this group ranged from 0 to 0.99 mL/g;
- Group 2 - Slightly sorbing (K_d = 1); K_d values ranged from 1 to 9.9 mL/g;
- Group 3 - Moderately sorbing (K_d = 10); K_d values ranged from 10 to 49.9 mL/g; and
- Group 4 - Strongly sorbing (K_d = 50); K_d values are 50 mL/g or greater.

Contaminant transport simulations were performed for each group, using the lowest value of the range. These results were used to design a limited sensitivity analysis (Volume Four, Section F.4.3.5).

The distribution coefficient for a given contaminant depends not only on the chemical characteristics of the contaminant but also on the chemistry of the aquifer (or vadose zone) and the water within. For example, a contaminant with a K_d value of 0 in saturated sands might have a nonzero K_d value in a clay-rich zone. There is a large uncertainty with regard to contaminant mobility in all the different material and water types at the Hanford Site. For example, the K_d value of U has a reported experimental value that varies from a low estimate of 0 to a high estimate of 79.3 mL/g (best estimate value is 0.6 mL/g) in Hanford Site sediments with waters of neutral to high pH, low ionic strength, low organic content, and toxic solutions. In Hanford Site sediments with waters of neutral to high pH levels, low ionic strength, low organic, and anoxic solutions, this same contaminant has a reported experimental value that varies from a low estimate of 100 to a high estimate of 1,000 mL/g (best estimate value is 100 mL/g) (Kaplan et al. 1994).

Given the uncertainty in the mobility of U, U was initially assumed to have a zero K_d. Assuming a high K_d would mean the contaminant did not reach groundwater within the 10,000-year period of interest.

Vadose zone simulations show that U with an assumed K_d of zero does reach groundwater within the 10,000-year period of interest for all the alternatives and that drinking water standards are potentially exceeded. Based on these results, the sensitivity of the U mobility assumption can be better understood with additional simulations with slightly higher values of K_d. Vadose zone simulations indicate that contaminants with a K_d of 0.125 mL/g do not reach the groundwater within the 10,000-year period of interest, using the Ex Situ Intermediate Separations alternative as the base case.

Future Groundwater Flow Direction

Under present land use conditions, groundwater flow direction and gradient on the Hanford Site is dynamic and changes primarily in response to wastewater disposal to the vadose zone and future land-use changes. Other factors could influence groundwater flow and gradient to a lesser degree. These factors include irrigation to the west of the Site and water level in the Columbia and Yakima Rivers.

The groundwater impact assessment for the TWRS EIS was based on a conceptual model with the following salient features: 1) water movement from surface infiltration, tank releases, and other near-surface sources is through the vadose zone, into the underlying aquifer, and ultimately to the Columbia River, 2) flow and transport of water and contaminants in the vadose zone and underlying aquifer are by advection through the interstitial pore spaces of the sediments, 3) the Columbia and Yakima Rivers form hydraulic boundaries: the Yakima River recharges the unconfined aquifer in the southern part of the Site and the Columbia River receives discharge from the unconfined aquifer, 4) the Cold Creek and Dry Creek valleys recharge the unconfined aquifer, part of which is derived from infiltrating irrigation waters to the west of the Site, 5) the Rattlesnake Hills to the west of the Site are a no-flow boundary, and 6) natural infiltration on the Hanford Site is assumed to be zero. This resulted in an expectation that most of the contaminants from the tank sources would move in a west to east/southeast direction with a small amount flowing northerly through the gap between Gable Butte and Gable Mountain. The December 1979 groundwater level data on which the impact assessments were based are the most recently available groundwater levels consistent with the conceptual model and have been extensively used and tested by other investigators (Wurstner-Devary 1993).

The December 1979 groundwater level data represent a period of relative steady conditions but also a period in which there were major groundwater mounds on the Site. These mounds are associated with wastewater disposal to B Pond, U Pond, and Gable Mountain Pond. Gable Mountain Pond has been closed, and waste disposal to the U and B Ponds has diminished. Both of these ponds ultimately will be closed. The groundwater mounds present in December 1979 have diminished with these changes and ultimately will totally dissipate.

The appropriateness of the December 1979 groundwater level data as a basis for impact analysis was tested in two ways: 1) qualitatively, by comparing the December 1979 groundwater level surface with predicted Site groundwater levels prior to Site development (i.e. hindcast) and 2) quantitatively, by calculating future Site groundwater levels using the VAM2D model and the same assumptions of boundary conditions and infiltration as used for the impact analysis, except that there was no water inflow from Site wastewater disposal to the vadose zone. Contaminant concentrations and associated risks were predicted for the Ex Situ Intermediate Separations alternative using this "no mound" predicted future flow field.

The differences among the December 1979 groundwater levels as simulated by the CFEST model (Volume Four, Figure F.2.4.2), the interpolated and contoured groundwater levels based on individual groundwater levels measured in site monitoring in December 1979, and the December 1979 groundwater levels as simulated by the VAM2D model were insignificant. The inferred groundwater flow directions in the hindcast (Figure K.4.2.1) were similar to the December 1979 simulated groundwater levels (Volume Four, Figure F.4.3.1). Groundwater flow directions inferred in the December 1979 representation were generally southeast/east, with a small component flowing northeast through the gap between Gable Butte and Gable Mountain. Groundwater flow directions inferred in the hindcast were due east, with a slight component of flow to the southeast and a slight component flowing northeast through the gap between Gable Butte and Gable Mountain.

The appropriateness of the December 1979 groundwater levels as a basis for impact analysis was examined quantitatively by predicting future groundwater levels assuming no impacts (e.g., groundwater mounds) from Site wastewater disposal and analyzing the associated risks for the Ex Situ Intermediate Separations alternative. Future groundwater levels were predicted by a steady-state simulation of the groundwater flow system assuming no inflow from Site wastewater discharges. These wastewater discharges were active in December 1979 and their estimated flow rates are provided in Volume Four, Table F.2.4.1. All the sites listed in this table, except the Rattlesnake Mountain Springs site, are waste disposal sites. The predicted future groundwater levels for these assumed conditions are provided in Figure K.4.2.2.

The future predicted groundwater levels, the December 1979 groundwater representation, and the hindcast all were very similar. As expected, the groundwater mounds from U Pond and B Pond evident in the December 1979 groundwater levels are not evident in Figure K.4.2.2. Recharge on the western portion of the Site from the valley out of the Rattlesnake Hills, coupled with the relatively low hydraulic conductivity of the sediments west of the 200 West Area, resulted in a relatively large groundwater gradient as indicated by the close contour spacing in that area. The gradient magnitude and direction in the area midway between 200 West and 200 East to the Columbia River on the east side of the Site were similar to the hindcast, which indicated a primary easterly flow direction from the 200 Areas.

The dissipation of the groundwater mounds, which would occur when the wastewater discharge was terminated, and the overall groundwater level drop, resulted in a larger area of Gable Mountain extending above the groundwater table. This difference in the Gable Mountain area above the groundwater table for the December 1979 groundwater levels and the forecasted "no mound" groundwater levels is illustrated in Figure K.4.2.2. This resulted in a slightly smaller aquifer area in which contaminants released from the waste tanks would dilute. The change would tend to prevent contaminants from diluting as quickly in the area immediately east of the 200 East Area, compared to the prediction based on the December 1979 groundwater levels. The larger Gable Mountain area above the groundwater table was predicted to extend to the northern portion of the 200 East Area, including the area around waste tank source area 1ESS. For comparison purposes, the aquifer in this area (Figure K.4.2.2) was assumed to be thicker by approximately 1 to 3 m (3 to 10 ft). This was necessary to simulate the transport of contaminants from the 1ESS source area through the aquifer. This adjustment to aquifer thickness may have artificially resulted in higher contaminant concentrations in the area near 1ESS.

Figure K.4.2.1 Hindcast of Water Levels in the Unconfined Aquifer

Figure K.4.2.2 Calculated Future Groundwater Levels in the Unconfined Aquifer After Effects from Discharge of Waste Water Have Dissipated

Section K.7.5 compares the calculated risks for the Ex Situ Intermediate Separations alternative based on December 1979 groundwater levels with those based on the predicted future groundwater levels shown in Figure K.4.2.2.

Climate Change

A climate change scenario was examined that included the return of an ice age. At present, the earth is in an interglacial phase. A transition to a glacial climate during the next few thousand years is highly unlikely. Such a transition during the next 10,000 years is more probable. Over a million-year time scale the global climate is virtually certain to pass through several glacial-interglacial cycles (National Research Council 1995).

Three potential changes associated with an ice age would likely impact waste disposed of onsite. These include 1) a cooler, wetter climate during early and late phases of the ice age that would increase infiltration through the waste and cause a faster movement of contaminants from onsite disposal locations to the Columbia River; 2) a cold, dry climate during the middle phase of the ice age that would reduce infiltration through the waste and slow migration of waste to the Columbia River; and 3) a catastrophic flood that would reach the Central Plateau and dislodge and scatter waste from the disposal site. During previous ice ages, ice dams have formed on upper tributaries of the Columbia River. These dams, when broken through, have resulted in floods of up to 2E+06 m^3 (5E+08 gal) of water in a period of a few weeks compared to the present average flow of the Columbia River of about 1E+05 m^3/year (3E+07 gal/year).

Such floods would be likely to impact any waste disposed of near the surface on the Hanford Site, scouring out waste sites to a depth of several meters and then redepositing waste from the tanks throughout the Pasco Basin.

Radioactive decay would have reduced the hazard from wastes disposed of onsite under all of the alternatives by the time of the postulated glacial flood in the next 40,000 to 50,000 years. For all of the alternatives, peak impacts on groundwater beneath the 200 Areas would have occurred at 210 to 350 years from the present for the No Action and Long-Term Management alternatives for K_d=0 and at 3,600 to 8,900 years from the present for all other alternatives. Because of the low concentrations of Pu and other radionuclides that would remain at the time of the postulated flood, the radiological consequences of a glacial flood would be small in comparison to the effects of the flood itself (DOE 1987).

One-Dimensional Flow

Two-dimensional or three-dimensional simulations of contaminant flow and transport in the vadose zone could provide more accurate estimates of contaminant arrival time, peak time, and peak concentrations (compared to one-dimensional simulations), provided that the spatial vadose zone hydraulic and transport properties were known. However, adequate knowledge of these parameters for two- or three-dimensional modeling currently is not available.

The one-dimensional simulations provided for this assessment were conservative and resulted in comparable estimates for each alternative. The simulations were conservative compared to two- or three-dimensional simulations using the same vadose zone properties. Because two- or three-dimensional flow and transport simulations allow for lateral flow and transport (slowing vertical movement), the transport times for the one-dimensional simulations were as fast or faster and the peak concentrations were higher because all transport and flow were in one direction only: downward within a uniformly porous medium.

Contaminants were assumed to move downward by advection with infiltration from precipitation and dissolution and leaching from tanks. The flow of water and transport of contaminants in the vadose zone would principally be in the vertical direction because of the hydraulic gradient and geologic structure (layering) in the vadose zone, which was assumed insufficient to result in extensive lateral spreading. Therefore, only one-dimensional modeling was performed in the vadose zone assuming a uniformly porous media and uniform hydraulic gradient.

Releases to the Soil During Retrieval

The ex situ alternatives were all assumed to result in contaminant releases from SSTs during retrieval operations. Each SST was conservatively assumed to lose 15,000 L (4,000 gal) during retrieval for a total of 2E+06 L (6E+05 gal) from the 149 SSTs. This assumption was based on current information from the waste retrieval program and the assumption that the average leakage volume from an SST would be one order of magnitude lower than the maximum release volume estimated for tank 241-C-106 during sluicing operations (DOE 1995d).

Based on the nominal retrieval scenario, all of the ex situ alternatives would have a contaminant first arrival time at the vadose zone/groundwater interface of approximately 1,000 years because of losses during retrieval. The lower bounding retrieval scenario would not change the time of release, and the contaminant first arrival time would not be expected to change either.

The rising limb of the concentration versus time curves at the vadose zone/groundwater interface (see Volume Four, Figure F.3.5.1 for characteristics of the ex situ alternatives) would shift to the right and calculated peak concentrations would be lower and could occur slightly later. Even though retrieval releases occur early compared to residual releases, the maximum peaks for the lower bounding scenario could be somewhat lower because the total mass released would be lower.

The following general alternative-specific assumptions were made for the modeling effort.

General Assumptions

- For the radioactive contaminants, the mass was estimated for each isotope based on the decay of that isotope to

December 31, 1995.

- Some contaminants in the tank inventory are of little importance and were not considered further in the groundwater assessment (Volume Four, Table F.2.2.3 provides a list of these contaminants).
- Contaminants were assumed to be released by their desorption and dissolution into pore fluids (this assumption holds for tank saltcake/sludge (No Action), grouted, and vitrified waste forms) and then moved by advection and diffusion from the waste source into the surrounding natural material or engineered barrier. Contaminants that are insoluble were assumed not to leach to groundwater.
- The LAW disposal facility was considered one source area even though 41 vaults are anticipated. The vaults would be covered with a continuous Hanford Barrier and the contents of each vault were assumed similar.
- The 177 tanks were divided into eight source areas based on configuration, tank proximity, and groundwater flow direction.
- Ingrowth of decay products was not calculated.
- No preferential flow paths (e.g., macropore flow) exist in the vadose zone.

1. No Action (Tank Waste) and Long-Term Management alternatives assumptions included the following.

- Releases to the groundwater system were associated with the complete inventory of contaminants in the waste tanks (Volume Four, Table F.2.2.2) except for insoluble contaminants.
- Infiltration would be 5 cm/year (2 in./year) initially and throughout the period of interest.
- Contaminant releases for the five SST source areas were assumed to begin at the end of institutional control.
- Contaminant releases from the three DST source areas were assumed to begin 100 years after the end of institutional control.
- The duration of this release was based on a congruent dissolution model. In this model, all constituents in the waste inventory were assumed to be released in proportion to the most abundant material in the waste inventory, nitrate. The concentration of nitrate is 360 g/L (Serne-Wood 1990). The initial unit concentration assumed in modeling for K_d groups 1 and 2 (K_d equals zero and one) was 400 g/L. The only difference between these alternatives is that under the Long-Term Management alternative, DSTs would be replaced during the institutional control period and assumed to begin leaking 100 years after the institutional control.

- In Situ Fill and Cap alternative assumptions included the following.

- Releases to the groundwater system were associated with the complete inventory of contaminants in the waste tanks (Volume Four, Table F.2.2.2).
- The initial vadose zone flow field was based on an infiltration rate of 5 cm/year (2 in./year).
- In 1997, the infiltration rate was assumed to decrease to 0.5 cm/year (0.2 in./year) in response to Hanford Site activities and decrease again to 0.05 cm/year (0.02 in./year) after the Hanford Barrier was installed. The Hanford Barrier was assumed to have lost integrity 1,000 years after installation, which would cause infiltration to increase to 0.1 cm/year (0.04 in./year) throughout the remainder of the 10,000-year period of interest.
- Five hundred years after the Hanford Barrier was installed, contaminant releases for the eight tank source areas were assumed to begin (NRC 1994).
- The principal constituent of the waste would be nitrate and the congruent dissolution release model was used to estimate release from the waste, which was the same approach as described for the No Action and Long-Term Management alternatives. The dissolution concentration of nitrate was assumed to remain constant at 360 g/L (Serne-Wood 1990), regardless of the water flux. The initial unit concentration assumed in modeling was 400 g/L.
- The initial contaminant inventory and concentrations were the same as for the No Action and Long-Term Management alternatives.

- In Situ Vitrification alternative assumptions included the following.

- Releases to the groundwater system were associated with the contaminants in the waste tanks, but the vitrification process would result in a different waste form (Volume Four, Table F.2.2.4).
- The initial vadose zone flow field was based on an infiltration rate of 5 cm/year (2 in./year).
- The infiltration rate was assumed to decrease to 0.05 cm/year (0.02 in./year) after the Hanford Barrier was

installed. The Hanford Barrier was assumed to lose integrity 1,000 years after installation, which would cause infiltration to increase to 0.1 cm/year (0.04 in./year) throughout the remainder of the 10,000-year period of interest.

- Five hundred years after the Hanford Barrier was installed, contaminant releases for the eight tank source areas were assumed to begin (NRC 1994).
- The release model for the vitrified mass was based on a constant total mass loss rate of 1.0E-03 g/m^2 per day (Shade et al. 1995). The mass loss rate was independent of the water flux from recharge. The composition of the vitrified mass was assumed to be identical to the soda-lime glass formed in the Ex Situ No Separations alternative (WHC 1995c). The release concentration of contaminants was then assumed to be proportional to their concentration in the soda-lime glass. Because the total mass loss rate would be constant, the composition of the released solution would be unaffected by the recharge rate. Because the infiltration rate would double after the barrier lost integrity, the mass flux would increase proportionately. The low value of the total mass loss rate, combined with the very large quantity of vitrified mass, would result in a release time measured in millions of years.

- Ex Situ Intermediate Separations alternative assumptions included the following.

- Releases to the groundwater system were associated with 1) releases during retrieval from the SSTs; 2) releases from residuals that could not be removed from the waste tanks; and 3) releases from the LAW disposal facility.
- The amount of liquid released from each SST during retrieval operations would be 15,000 L (4,000 gal). The mass associated with retrieval operations at each source area is provided in Volume Four, Table F.2.2.5.
- The tank residual materials were assumed to be 1 percent of those for the No Action and Long-Term Management alternatives (Volume Two, Appendix A).
- The mass associated with the contaminants in the LAW vaults was based on the vitrified form of the retrieved waste (Volume Four, Table F.2.2.6).
- The initial vadose zone flow field was based on an infiltration rate of 5 cm/year (2 in./year) for tank source areas and the LAW source area.
- In 1997 the infiltration rate was assumed to decrease to 0.5 cm/year (0.02 in./year) in response to Site activities and decrease again to 0.05 cm/year (0.02 in./year) after the Hanford Barrier was installed at tank source areas and the LAW source area. The Hanford Barrier was assumed to lose integrity 1,000 years after installation, which would cause infiltration to increase to 0.1 cm/year (0.04 in./year).
- Contaminant releases for the five SST source areas were assumed to occur 1) during retrieval in 1997; and 2) from residual materials 500 years after Hanford Barrier construction.
- Contaminant releases for the three DST source areas were assumed to result from releases from residual materials 500 years after Hanford Barrier construction.
- Contaminant releases for the LAW facility were assumed to begin 500 years after the Hanford Barrier was constructed over the vaults (NRC 1994).
- The solubility of each contaminant for retrieval releases and tank residuals would be proportional to the solubility of nitrate. For the tank source areas, the initial unit concentration assumed in modeling was 400 g/L.
- The release model for the glass cullet was based on a constant corrosion rate of 3E-06 cm/year (1E-06 in./year) (Jacobs 1996). This corrosion rate would be independent of the water flux from infiltration. The composition of the LAW glass was taken from the engineering data package for this alternative (WHC 1995j). The release concentration of the contaminants was assumed to be proportional to their concentration in the LAW glass. Because the total mass loss rate would be constant, the composition of the released solution would be unaffected by the infiltration rate. Because the infiltration rate would double after the barrier lost integrity, the mass flux would increase proportionately. The low value of the corrosion rate, combined with the large quantity of vitrified mass, would result in a calculated release time of 170,000 years.
- For the tank source areas, the initial contaminant concentrations were the same as for the No Action and Long-Term Management alternatives. The initial concentrations for the LAW disposal facility are provided in Volume Four, Table F.2.2.17.

- Ex Situ No Separations alternative assumptions included the following.

The assumptions for this alternative were the same as for the tank retrieval and tank residual components of the Ex

Situ Intermediate Separations alternative (i.e., 1 percent of tank waste was assumed to remain as a residual in the tanks).

- Ex Situ Extensive Separations alternative assumptions included the following.

The assumptions for this alternative were the same as for the tank retrieval and tank residual components of the Ex Situ Intermediate Separations alternative (i.e., 1 percent of tank waste was assumed to remain as a residual in the tanks). For this alternative, the contaminant inventory in the LAW vaults would be smaller than estimated for the LAW vault component of the Ex Situ Intermediate Separations alternative (see Volume Four, Table F.2.2.7).

- Ex Situ/In Situ Combinations 1 and 2 alternatives assumptions included the following.

These alternatives would incorporate all of the assumptions listed for the Ex Situ Intermediate Separations alternative and the In Situ Fill and Cap alternative except as noted as follows. For the tanks remediated ex situ:

- Releases to the groundwater system would be due to losses during retrieval (Volume Four, Table F.2.2.8).
- Residual waste that could be left in a tank after retrieval was assumed to be 1 percent of the initial tank inventory.
- The 1 percent residual waste was added to the inventory of tanks remediated in situ.

For the tanks remediated in situ:

- Releases to the groundwater system would be due to leaching from the waste form within the tanks (Volume Four, Table F.2.2.9). Table F.2.2.9 contains the initial waste inventory.
- Phased Implementation alternative assumptions included the following.
- There would be no groundwater impacts associated with the first phase of this alternative because there would be no contaminant releases from the tanks.
- The assumptions for the total alternative would be the same as those for the Ex Situ Intermediate Separations alternative.

K.4.2.2 Parameter Sensitivity

Parameter sensitivity was investigated for the following areas:

- The effect of higher glass surface areas for the In Situ Vitrification alternative;
- The effect of changing the performance period of the Hanford Barrier from 1,000 to 500 years;
- The effect of the decay of the potentiometric head from groundwater mounding due to discharge to the Hanford Site ponds;
- The effect of variations in infiltration rate; and
- The effect of variations in distribution coefficient (K_d).

In Situ Vitrification Surface Area

As part of the parameter sensitivity analysis, the vitrified glass surface area was assumed to have doubled to represent the case where extensive cracking of the waste form occurred. This higher surface area doubled the corrosion rate. The predicted U-238 concentrations in groundwater at 5,000 and 10,000 years, respectively, at the higher corrosion rate are provided in Figures K.4.2.3 and K.4.2.4. Comparing these figures with Volume Four, Figures F.4.3.4 and F.3.4.5, which were based on the original corrosion rate, shows that the estimated contaminant concentrations in groundwater at the higher surface area are almost indistinguishable from those calculated for the base case analysis.

500-Year versus 1,000-Year Hanford Barrier

There is some uncertainty concerning the long-term performance of the Hanford Barrier that would be placed over the tanks and the LAW vaults. This uncertainty was investigated using the In Situ Fill and Cap alternative as a basis for comparison. The Hanford Barrier was assumed to degrade 500 years after placement instead of after 1,000 years as assumed in Volume Four, Section F.3.3. At 500 years, the water flux through the Hanford Barrier was assumed to double from 0.05 to 0.1 cm/year (0.02 to 0.04 in./year). The calculated nitrate concentration at selected locations within the unconfined aquifer is provided in Figure K.4.2.5. Comparing Figure K.4.2.5 with Volume Four, Figure F.3.3.3 shows no significant difference in peak concentrations of nitrate, the most abundant and mobile contaminant. The time of arrival of contaminants (using nitrate as an example) is slightly earlier for the 500-year Hanford Barrier. A comparison of Figures K.4.2.6 and Volume Four, Figure F.3.3.16 indicates that U-238 concentrations in groundwater at 10,000 years from the present are low for both cases, and for the 500-year Hanford Barrier, U-238 concentrations are lower by a factor of approximately 5 to 10. This occurs because the higher water flux through the 500-year Hanford Barrier would allow U-238 to travel faster through the vadose zone and the groundwater system.

Variations in Infiltration Rate

An infiltration rate of 5 cm/year (2 in./year) was assumed as the initial condition for all the alternatives. For those alternatives involving active remediation, such as the In Situ Vitrification and Ex Situ Intermediate Separations alternatives, the infiltration rate was assumed to be reduced to 0.5 cm/year (0.2 in./year) during the remediation period (e.g., during waste removal and cap construction).

The assumed infiltration rate of 5 cm/year (2 in./year) is an appropriate value that is within the range of reported values. Prior to Site development in the early 1940's, the infiltration rate was likely much lower, on the order of a few millimeters per year, characteristic of the 200 Areas Plateau under naturally vegetated conditions. As the tank farms were constructed, the natural vegetation was removed and the vicinity around the tanks was covered with sand and gravel. The current infiltration rate in the vicinity of the tanks is believed to be on the order of 10 cm/year (4 in./year). This higher infiltration rate would be greatly reduced with the installation of a cap or return to natural shrub-steppe type ground cover.

Figure K.4.2.3 Predicted Uranium-238 Concentrations in Groundwater at 5,000 Years for the In Situ Vitrification Alternative (High Glass Corrosion Concentration)

Figure K.4.2.4 Predicted Uranium-238 Concentrations in Groundwater at 10,000 Years for the In Situ Vitrification Alternative (High Glass Corrosion Concentration)

Figure K.4.2.5 Predicted Nitrate Concentration in Groundwater at Selected Locations for the In Situ Fill and Cap Alternative (500-Year Cap)

Figure K.4.2.6 Predicted Uranium-238 Concentrations in Groundwater at 10,000 Years for the In Situ Fill and Cap Alternative (500-Year Cap)

To estimate the sensitivity of the overall results (e.g., concentration of tank wastes predicted in groundwater) to the initial infiltration rate of 5 cm/year (2 in./year), an alternative infiltration scenario was developed for the In Situ Fill and Cap alternative. For this scenario, the initial infiltration rate was assumed to be 1 cm/year (0.4 in./year) for the 200 Areas Plateau under natural vegetation. It was assumed that in 1955, the infiltration rate increased to 10 cm/year (4 in./year) and would remain at this rate until 2023, after the cap construction was complete for all source areas. At this time, the infiltration rate would be reduced to 0.05 cm/year (0.02 in./year) and would remain at this level for 1,000 years. All other aspects of the In Situ Fill and Cap alternative are the same as assumed in Volume Four, Section F.2.2.3.3. Contaminant flow and transport through the vadose zone were simulated using this infiltration scenario for three of the eight source areas. The source areas and their total vadose zone thicknesses (from the base of the tanks to the water table) are as follows:

Source Area	Vadose Zone Thickness m (ft)
1WSS	51 (170)
2WSS	48 (160)

5EDS	68 (220)

These source areas were chosen because they bound the range of vadose zone thicknesses. When the results of this alternative infiltration scenario, graphed as concentration versus time, were compared to the nominal case (i.e., initial infiltration rate of 5 cm/year [2 in./year]), they were nearly identical, with less than a 1 percent difference between estimated concentrations.

Variations in Distribution Coefficients

As explained in earlier sections, the distribution coefficient (K_d) for a specific contaminant is an indication of the mobility of the contaminant within the aquifer system. Contaminants with lower K_ds are more mobile, and contaminants with higher K_ds are less mobile. Contaminants with K_ds of 0 and 1 mL/g have been calculated to arrive at the interface between the vadose zone and groundwater within the 10,000-year period of interest for both the No Action and Long-Term Management alternatives. For the other alternatives, only contaminants in K_d Group 1 (K_d equal to 0) have been calculated to arrive at the vadose zone groundwater interface within 10,000 years because the influx of precipitation into the waste would be greatly reduced by the cap. Not all the contaminants in K_d Group 1 have a K_d of zero. Uranium is an example of a contaminant that, while conservatively placed in K_d Group 1, likely has a K_d between zero and one. The Ex Situ Intermediate Separations alternative was selected as representative of alternatives that incorporate a cap and was used as the basis for estimating the sensitivity of contaminant transport for K_d values between zero and one.

The sensitivity of contaminant travel time through the vadose zone to various K_d values was evaluated by varying K_d for this alternative and for the 1WSS source area and then tabulating the arrival time at the vadose zone/groundwater interface. The range of K_d values selected for analysis and the times of first arrivals calculated by the model is as follows:

K_d Value (mL/g)	First Arrival at Vadose Zone/ Groundwater Interface (years)
0.00	1,500
0.05	5,300
0.075	7,000
0.10	8,600
0.125	10,000

For K_d greater than 0.125 mL/g, first arrival did not occur until just after 10,000 years. This is important for contaminants such as U that are reported to have K_d values of approximately 0.6 mL/g at the Hanford Site, as they would not reach the groundwater within the period of interest for alternatives that include a cap.

K.4.3 TRANSPORT IN SURFACE WATER

The primary sources of uncertainty in estimating surface water transport are associated with the rate of dilution of contaminants in groundwater entering the Columbia River. These sources are the turbulence of river flow, which depends on the velocity; irregularities in the stream channel, including bends; and the width of the river. All these factors ultimately depend on the total flow in the river at the point(s) where contaminated groundwater would be discharged.

K.4.4 TRANSPORT IN AIR

Various assumptions and other factors can introduce uncertainty into air dispersion modeling studies. With regard to the modeling performed to analyze air impacts from the various EIS alternatives, these uncertainties can be separated broadly into the following categories:

- Uncertainty inherent in the air dispersion models;
- Uncertainty in data used as model inputs; and
- Uncertainty in interpretation of model output.

These categories are discussed in more detail in the following text.

K.4.4.1 Air Dispersion Modeling

Air dispersion models are mathematical tools designed to estimate pollutant concentration and/or deposition at specific locations. These predictions are based on various input parameters and physical assumptions, such as the following:

- Pollutant release characteristics (emission rate, temperature, flow rate);
- Meteorological conditions (ambient temperature, mixing height, stability, wind speed and direction, atmospheric temperature, and wind speed profile); and
- Pollutant transport behavior (dispersion, plume rise, interaction with terrain).

In an ideal case, the values entered into the model for these known parameters will closely duplicate the range of conditions that exist for a particular scenario. However, the stochastic nature of the atmosphere results in other unknown factors (e.g., wind perturbations) that influence the dispersion at a particular time or place. It has been estimated that even when the known conditions are exactly duplicated in the model, the unknown factors can contribute to variations in concentration as much as ±50 percent.

Gaussian air dispersion models are accurate within a factor of two when properly executed with accurate data. In general, models are more reliable when estimating long-term average concentrations as opposed to short-term averages, and are reasonably reliable in estimating the highest concentration occurring, but are not capable of predicting the exact time or position of the occurrence. In other words, the highest concentration that can be expected in an area can be predicted with reasonable accuracy; the location and time that the maximum concentration will occur are less reliably predicted.

The air dispersion models used in this study are considered to be state-of the-art for regulatory modeling and are recommended by the U.S. Environmental Protection Agency (EPA) for this type of analysis. To compensate for the uncertainties in model results, conservative input values were used that provide conservative (higher than might occur under average conditions) results.

K.4.4.2 Model Input Data

Two types of input data were used for the air dispersion models: meteorological data and source data. Both types of input data are discussed in the following text.

Meteorological Data

Two types of meteorological data (i.e., long-term and short-term) were used in the dispersion modeling study. Long-term (i.e., annual) average concentrations were estimated using meteorological data collected at the Hanford Meteorological Station from 1989 to 1993. The assumption inherent in this choice is that these data represent future meteorological conditions. A 5-year record is generally accepted as an adequate sample set for modeling purposes. Although long-term climatic shifts may occur, many of the air pollutant emitting activities analyzed in this study are expected to occur within several decades of project initiation, which is a relatively short time frame on a climatic scale.

Therefore, the use of these data is not expected to adversely affect the results.

Typically, short-term average (i.e., 1- 3- 8- and 24-hour) concentrations are predicted using hourly meteorological measurements from a station located at or near the site of interest. Because appropriate data were not available for this study, a screening approach was taken, and a standard set of hourly meteorological conditions were incorporated in the modeling. These standard conditions are accepted by the EPA to encompass the range of atmospheric stabilities and wind speeds that could be expected to occur anywhere. Each combination of wind speed and atmospheric stability was assumed to occur in every possible wind direction. The predicted concentrations represent the highest value that could reasonably be expected to occur anywhere. This approach is conservative because the meteorological conditions leading to the reported result may not occur at the site for all wind directions.

Source Data

Data describing the location, emission rate, and emission characteristics of the sources were input to the models. Information concerning pollutant emission rates was derived from data packages supplied by the Site Management and Operations contractor and analyzed by the EIS contractor. In general, conservative values were used to develop emissions estimates.

The location of the pollutant emitting sources was not known with complete certainty in all cases. Pollutant emitting activities associated with the existing tank farms will occur in the present locations. However, the exact location of future facilities is subject to some uncertainty. In general, the closer a source to a receptor, the higher the predicted concentration at that receptor. As a consequence, if the eventual location of an emitting activity is closer to a plant boundary than depicted in the model, the impacts may be higher. Of course, if the activity is located farther from the boundary than depicted in the model, the impacts may be lower.

The temporal arrangement of the pollutant emitting activities affects the predicted concentrations as well. The predicted concentration at any receptor includes the contributions from each individual emitting source. To properly analyze a scenario, all the pollutant emitting activities that could occur at the same time must be considered. In general, most of the scenarios analyzed involved a period of facility construction followed by an operational period.

In some cases, an emitting source is expected to move from place to place as the project progresses. An example of this would be emissions related to remedial activities at tank farm locations. In most cases at a given time, work would be occurring at one or two of the possible 17 locations. Given these uncertainties, a conservative analysis was ensured by assuming that activities that may or may not overlap would occur simultaneously. In addition, activities that are expected to move from place to place were modeled as if occurring in the location producing the highest potential impact.

Sources were modeled as either point or area sources. Point sources were used to approximate pollutant releases from a stack or other fixed, functional opening, or vent. The dispersion algorithms used for point sources modify the effective release height to take into account plume buoyancy (from a heated release) and momentum (from vertical release velocity). Typically, area sources were used to approximate pollutant releases that would not occur at a single, well-defined point, but instead can be defined as occurring within a defined area. For instance, an area source could include many small fixed point sources that were too numerous to model individually, or could be made up of several mobile sources that could move about within the fixed area. In this study, the construction activities were represented as area sources. The classification of the sources into these two categories involved some degree of uncertainty as well as some assumptions. The models used different algorithms to represent dispersion from point and area sources, and the predicted concentration at a receptor could vary depending on the algorithm chosen. In general, these effects would be more noticeable at locations close to the source and tend to diminish as the distance between source and receptor increased.

K.4.4.3 Interpretation of Model Output

The short-term model was run using screening meteorology to produce predicted maximum 1-hour average concentrations. These 1-hour average values were converted to 3- ,8-, and 24-hour average concentrations, when appropriate, to compare to applicable standards. This was accomplished by applying conversion factors to the 1-hour average values. Consistent with modeling guidelines (EPA 1988), the factors of 0.9, 0.7, and 0.4 were applied to convert to 3-, 8-, and 24-hour averages, respectively. These factors involve an implied assumption regarding the persistence of the meteorological condition producing the highest 1-hour impact. In other words, conservative meteorological conditions that produced the highest 1-hour concentration can be expected to persist for most of a 3-hour period, and to a lesser degree over an 8- or 24-hour period. The modeling guidelines indicate a range of values for each conversion factor: the 3-hour conversion factor can range from 0.8 to 1.0, the 8-hour factor from 0.5 to 0.9, and the 24-hour factor from 0.2 to 0.6. Use of the midpoint values was considered appropriate for this study.

Chronic (Routine) Air Dispersion

In the routine risk assessment, the airborne transport is based on the 9-year average (1983 to 1990) wind data measured at 10 m (33 ft) and 61 m (200 ft) at the Hanford Meteorological Station (HMS) in the 200 Areas. The variation in the chronic atmospheric dispersion coefficient (Chi/Q) was estimated using wind data collected at 10 m (33 ft). The values for joint frequency were computed by GXQ Version 4 (Hey 1993 and 1994).

The locations of the onsite maximum individuals were taken to be 100 m (330 ft) from the release point for ground level releases, and 800 m (2,640 ft) for stack releases. The locations of the site boundary maximum individuals were averages of the distances from the Plutonium Finishing Plant (PFP) and the Plutonium-Uranium Extraction (PUREX) Plant. These distances are shown in Table K.4.4.1.

The maximum normalized time-integrated exposures (Chi/Q) for each year estimated with available data are listed in Table K.4.4.2. The observed variation in the annual Chi/Q at the chosen locations is approximately a factor of 2. Population weighted Chi/Q values are subject to similar variation. The observed variation in population-weighted Chi/Q values is less than a factor of 2 (Table K.4.4.3).

Acute (Accident) Air Dispersion

Bounding Chi/Q values were generated consistent with the methods described in Nuclear Regulatory Commission (NRC) Regulatory Guide 1.145 (NRC 1982). The Chi/Q values were calculated assuming the receptor was located at the peak concentration. Because atmospheric conditions fluctuate, a bounding atmospheric condition was considered to be that which causes a downwind concentration of airborne contaminants that is exceeded for only a small fraction of time due to weather fluctuations. Regulatory Guide 1.145 defines this fraction as 0.5 percent for each sector or 5 percent for the overall site. The site is broken up into 16 sectors, which represent 16 compass directions (e.g., S, SSW, SW, ESE, SE, SSE). Chi/Q values are generated for weather conditions that result in downwind concentrations that are exceeded only 0.5 percent of the time in the maximum sector, or 5 percent of the time for the overall site. These Chi/Q values also are referred to as 99.5 percent maximum sector or 95 percent overall site Chi/Q values. The greater of these is called the bounding Chi/Q value and was used to assess the bounding dose consequences for accident scenarios presented in this EIS (Table K.4.4.4). These bounding Chi/Q values represent minimum dispersing conditions that result in maximum downwind concentrations (i.e., concentrations that are exceeded only a small fraction of the time). These Chi/Qs will result in conservative estimates of potential accident consequences.

Table K.4.4.1 Site Boundary Distance from PFP and PUREX

Table K.4.4.2 Maximum Individual Annual Chi/Q for Selected Receptor Locations

Table K.4.4.3 Maximum Population - Weighted Annual Chi/Q for Selected Receptors Locations

Annual average Chi/Q values also were generated for each sector. The sector with the highest annual average Chi/Q value was selected as presented in Table K.4.4.5. These values were used in conjunction with nominal source terms to calculate nominal dose consequences. The annual average Chi/Q values were calculated assuming the receptor was located at the peak concentration. The dose calculated using the annual average Chi/Q value for a particular sector represented the average dose to an individual located in that sector, accounting for the frequency of time that the wind blew in that direction during the year. This, it accounted for the fact that the receptor in a particular direction would experience no dose if the wind was blowing in a different direction at the time of the accident, and would receive a dose higher or lower than the annual average if the wind was blowing in the direction of the receptor. In summary, the dose based on annual average meteorology represented the average that an individual in a particular sector would receive for all meteorological conditions over the year. The ratio between the bounding and the annual average meteorology is presented in Table K.4.4.6.

Table K.4.4.4 Bounding Meteorology Chi/Q Values Generated for Ground Level Releases from Tank Farms

Table K.4.4.5 Annual Average Meteorology Chi/Q Values Generated for Ground Level Releases from Tank Farms

K.5.0 UNCERTAINTIES IN HUMAN EXPOSURE ASSESSMENT

In addition to source terms and contaminant transport, exposure assessment contributes to uncertainty in the risk estimates. Some of the contributing parameters are lifestyle, diet, land use patterns, exposure pathways, exposure frequency and duration, and biotransfer/bioaccumulation factors. These uncertainties are discussed in the following sections.

Humans may be exposed to hazardous substances in many ways, which may cause some degree of risk to health. The uncertainty in risk for each receptor increases as the variety of potential exposures increases. The risk analysis in the TWRS EIS includes multiple exposure scenarios that cover a wide spectrum of exposure pathways. Therefore, the likelihood that real future exposures lie outside the range estimated in the EIS is small.

The post-remediation land user scenario describes the long-term risk to an individual and the whole population from restricted to unrestricted use of the land. The Native American and residential farmer receptors use land without any restrictions, and the industrial worker and recreational users use land with some limited restrictions. The health impacts of short-term exposure (routine and accidental) that would occur during remediation add a layer to the analysis that reduces the systematic uncertainties in the risk assessment. Another health impact, exposure to hazardous substances by inadvertent intrusion, characterizes a different exposure category.

The uncertainty in exposure assessment is more fully characterized by incorporating several exposure scenarios and categories. The uncertainties within each of these scenarios and categories are diverse and can be large. There is a need to analyze each scenario and category on an individual basis. The following sections discuss the uncertainty in the risk assessment for post-remediation land use, routine and accidental exposures during remediation, and post-remediation intrusion.

K.5.1 POST-REMEDIATION LAND USER

This section describes the uncertainty analyses for the risks to potential post-remediation land users. Scenarios evaluated under the post-remediation land user scenario include: the Native American, residential farmer, industrial worker, and intruder.

K.5.1.1 Modular Risk Assessment Approach

The method used to assess the post-remediation risk at the Hanford Site was a modular risk assessment (MRA) approach. The MRA approach separates the four basic components of the risk assessment (i.e., source, transport, exposure, and risk) into discrete modules that can be assessed independently and then combined. This process is described by the following equation:

Risk = Source Unit Transport Factor Unit Risk Factor

This section focuses on the results of the uncertainty and sensitivity analysis as they pertain to the unit risk factor (URF). The uncertainty analyses with respect to the source term and the unit transport factors are presented in other sections of this appendix.

The calculation of the URF is simplified by dividing the equation into two terms, one term containing parameters independent of contaminant properties (i.e., summary intake factors) and the other term containing parameters dependent on contaminant-specific properties.

URFs are described in terms of exposure pathways, toxic endpoint (carcinogenic chemical, noncarcinogenic chemical, and radionuclide carcinogen), and exposure parameters (i.e., intake rate, exposure frequency, and exposure duration).

The URF approach involved structuring the intake equations for each receptor and exposure pathway so that contaminant-independent parameters were separated from the contaminant-specific parameters.

The pathway-specific slope factor is a toxicological contaminant-specific parameter that is specified by the regulatory agencies and generally not subjected to an uncertainty analysis, although there is considerable uncertainty associated with this parameter.

The intake term may be further described in terms of the following equation:

Where:

Intake = average daily intake of pollutant
C = concentration of pollutant
PF = pollutant-specific factor for media of concern
SIF = summary intake factor for given scenario

The uncertainties associated with the concentration term and other pollutant-specific factors are discussed in other sections of this appendix. The uncertainty associated with the SIF or intake term is the subject of this section of the report.

The SIF is a scenario-specific term and generally is derived from exposure factors published by the EPA for generating upper-bound (i.e., 95th percentile) point estimates of exposure. The use of these upper-bound estimates in calculating point estimates for human health exposure has been shown to result in "compounding conservatisms," which often has led to risk estimates that are highly unlikely to be experienced by anyone in a population near a site (Burmaster-Harris 1993). Therefore, a knowledge of the uncertainty associated with the SIF and exposure factors used to generate risk estimates is important to place the risk estimates in perspective.

One approach for establishing the uncertainty in the SIF and exposure parameters is to use a Monte Carlo-based approach (PNL 1993). In this approach, the Monte Carlo technique adds several steps to estimate both point values and full distributions for the exposures. These extended techniques make the analyses more informative to risk managers and members of the public by giving some perspective on the uncertainty behind the point estimates.

K.5.1.2 Monte Carlo Uncertainty Analysis

The first step in the Monte Carlo uncertainty analysis was to identify the exposure medium (air, soil, groundwater) and exposure pathway (e.g., ingestion, inhalation, vegetable consumption) driving the risk. The next step involved constructing equations that would both represent the shortcomings identified in EPA methodology and correspond with the site-specific conditions. These preliminary equations were used, along with readily available input ranges, to conduct a sensitivity analysis to determine which inputs should be focused on in characterizing input distributions for use in the Monte Carlo-based approach.

The results of the sensitivity analysis allowed the inputs to be ordered in terms of their impact on the intake term or SIF using the Monte Carlo methodology. The magnitude of the impact that an input had on the intake term or SIF was a function of both the inputs mathematical relationship to the SIF and the range identified for that input. The results of the sensitivity analysis were combined with an assessment of the quality of information available from the literature for characterizing each input. The final result of the sensitivity analysis was a list of those inputs that will receive special focus in characterizing distributions.

The next step in the Monte Carlo methodology was to generate continuous or discrete probability functions (PDFs) for all relevant inputs. In the Monte Carlo approach, each of many input variables can become a random variable with known or estimated PDF. Within this framework, a variable would take on a range of values with known probability. Some distributions, for instance, were based on known human variability and came into play in the analysis because of the uncertainty as to who will be involved in the scenario. Once the exposure models, variables, and constants for the models were defined, the next step was to use a suitable software to make a large number of realizations of the set of random variables in each model. For each realization, the computer drew one random value from the appropriate distribution for each of the random variables in the model and computed a single result. This computation was repeated a large number of times to produce complete distributions of modeled variables. Finally, the distributions were plotted and various statistical summaries of the results were produced to help interpret the data.

The final step in the development and evaluation of the Monte Carlo methodology was the generation of the SIF or intake distribution. The SIF generated using the EPA point estimate methodology then was compared to the distribution generated using the Monte Carlo approach. This comparison was useful in that the relative position of the point estimate on the probability density function provided a perspective as to the conservatism of the point estimate.

The computer software used in this Monte Carlo uncertainty analysis was Crystal Ball software program, which is an add-on to the Microsoft Excel spreadsheet program. The use of Crystal Ball software allows Excel spreadsheets to be incorporated directly into the Monte Carlo approach. The Crystal Ball program allows either Latin Hypercube Sampling or the default conventional sampling method usually used in Monte Carlo simulations. The default method generates random values for each distribution over the entire range defined for that distribution. This approach can accurately reflect the shape of distributions if enough iterations are completed in order to allow values in the more obscure tail regions of distributions to be sampled. The Latin Hypercube method divides distributions into regions of equal probability. Latin Hypercube Sampling was used in this evaluation to quickly stabilize the tail regions of the output distribution. This approach ensured that all regions of a distribution were sampled with equal frequency. Table K.5.1.1 provides a summary of the PDFs used in the Monte Carlo-based uncertainty analysis.

The number of iterations used in the Monte Carlo simulation was based on the work of Thompson (Thompson 1992). In this approach, a simulation is run twice, each time using 10,000 iterations. If the 95th percentiles from the resulting distributions differ by more than 1 percent from each other, the number of runs used in the simulation is increased until the differences between 95th percentile values falls below the arbitrary 1 percent mark. Runs of 10,000 iterations were found to produce stable risk distributions in this analysis.

Sections K.5.1.3 through K.5.1.9 provide the results of the Monte Carlo uncertainty analysis and sensitivity analysis as they pertain to the individual receptor of the specific exposure scenarios analyzed in the EIS. The uncertainties associated with the cumulative risk over 10,000 years for each exposure scenario are discussed in Section K.5.1.1.6.

K.5.1.3 Native American Scenario

The Native American scenario was intended to include a wide range of activities from traditional lifestyle activities (i.e., hunting and fishing) to contemporary lifestyle activities (i.e., irrigated farming). Specific activities include hunting, gathering, collecting, fishing, and processing of the catch along the shoreline, and pasturing of livestock, as well as ceremonial, educational, seasonal, social, and trade activities. A detailed description of the Native American scenario is provided in DOE (DOE 1996).

The focus of this section of the report is to evaluate the uncertainty associated with the SIF as it pertains to exposure pathways specific to the Native American scenario. The SIFs evaluated for the Native American scenario were based on Tribal input because currently there are no standards or data regarding Tribal-specific intake factors. Therefore, the SIFs for the Native American scenario were compared against the ICRP recommendations (e.g., ICRP 1975) or EPA standards (e.g., EPA 1989) for humans. This could result in more uncertainty than for the other scenarios that were based on EPA standards. The exposure pathways that would contribute the greatest risk to a Native American include: groundwater ingestion, meat and fish ingestion, and the inhalation of volatile compounds (i.e., while in a sweat lodge). Please refer to Volume Three, Section D.2.1.3 for a complete discussion of the risk associated with each exposure pathway in the Native American scenario.

Table K.5.1.1 Summary of Probability Density Functions

Uncertainty in the Groundwater Ingestion Summary Intake Factor

The Native American scenario groundwater ingestion SIF was based on exposures over a 70-year duration to an individual residing onsite. The exposed individual was assumed to ingest 3 L (0.8 gal) of water a day 365 days a year (DOE 1996). The groundwater ingestion SIF is expressed by the following equation:

Where:

SIF = Summary intake factor (liters)
IR = Ingestion rate (liters/day)
EF = Exposure frequency (days/year)
ED = Exposure duration (years)

Substitution of the fixed point estimate for IR, EF, and ED resulted in a groundwater ingestion SIF of 7.67E+04 L (DOE 1996).

The U.S. Army and EPA historically have used 2 L/day (0.5 gal/day) as an average water consumption rate (EPA 1989). However, the scientific literature suggests an average drinking water consumption rate of 1.4 L/day (0.37 gal/day) (EPA 1989). Burmaster has shown that drinking water ingestion rates follow a lognormal distribution with a mean value of 1.12 L/day (0.30 gal/day) and a standard deviation of 1.63 L/day (0.430 gal/day) (Burmaster 1992). For purposes of this uncertainty analysis, the drinking water ingestion rate was approximated by a triangular distribution. The maximum value was assumed to be 3 L/day (0.8 gal/day) (DOE 1996); most likely value 2 L/day (0.5 gal/day) (EPA 1989); and minimum value 1.1 L/day (0.29 gal/day) (Rosenberry-Burmaster 1992).

The exposure duration and exposure frequency parameters for the Native American scenario were assumed to follow distributions similar to those of United States populations. The time spent at a residence followed a lognormal distribution with a mean value of 4.55 years and a standard deviation of 8.68 years (Israeli-Nelson 1992). The exposure frequency for ingestion of drinking water was approximated using a triangular distribution with a maximum of 365 days/year, most probable value of 345 days/year and a minimum of 180 days/year (Smith 1994).

Monte Carlo uncertainty and sensitivity analyses were performed on the groundwater ingestion SIF. The sensitivity analysis indicated that the parameters that contributed the most to the uncertainty in the groundwater ingestion SIF as measured by rank order were exposure duration, ingestion rate, and exposure frequency. The results of the Monte Carlo analysis are summarized in Table K.5.1.2.

Table K.5.1.2 Native American Scenario Groundwater Ingestion SIF Estimates [1]

Table K.5.1.2 contrasts the mean and percentile estimates of the PDF for the groundwater ingestion SIF for the Native American scenario with the value derived using upper-bound fixed point estimates for IR, EF, and ED. The results show that the SIF derived using the upper-bound values lies above the 95th percentile of the SIF PDF. The mean of the SIF probability distribution was one order of magnitude lower than the fixed point estimate. This result suggests that the Native American scenario drinking water SIF derived using default parameters is an upper-bound estimate and may not be representative of the typical intake of a hypothetical future Native American resident.

Uncertainty in the Fish Ingestion Summary Intake Factor

The Native American scenario fish ingestion SIF was based on exposures over a 70-year duration to an individual residing onsite. The exposed individual was assumed to consume 1,080 g/day (2.4 lb/day) of fish for 365 days/year (DOE 1996). The fish ingestion SIF is expressed by the following equation:

Where:

SIF = Summary intake factor (kg)
IR = Ingestion rate (kg/day)
EF = Exposure frequency (days/year)
ED = Exposure duration (years)

Substitution of the default estimates for IR, EF, and ED resulted in a fixed point estimate for the fish ingestion SIF of 2.76E+04 kg (6.1E+04 lb) (DOE 1996). Consumption rates for recreationally caught fish from large bodies of water have a 50th percentile average of 30 g/day (1 oz/day) and a 90th percentile average of 140 g/day (0.3 lb/day) (EPA 1989). Therefore, for purposes of this scenario, the fish ingestion PDF was approximated by a triangular distribution. The maximum value was assumed to be 1,080 g/day (2.4 lb/day) (DOE 1996); most likely value 140 g/day (0.3 lb/day) (EPA 1989); and minimum value 30 g/day (1 oz/day) (EPA 1989).

The time spent at a residence followed a lognormal distribution with a mean value of 4.55 years and a standard deviation of 8.68 years (Israeli-Nelson 1992). The exposure frequency for ingestion of fish was approximated using a triangular distribution with a maximum of 365 days/year, most probable value of 345 days/year and a minimum of 180 days/year (Smith 1994).

Monte Carlo uncertainty and sensitivity analyses were performed on the fish ingestion SIF. The sensitivity analysis indicated that the parameters that contributed the most to the uncertainty in the fish ingestion SIF as measured by rank order were exposure duration, ingestion rate, and exposure frequency. The results of the Monte Carlo analysis are summarized in Table K.5.1.3.

Table K.5.1.3 Native American Scenario Fish Ingestion SIF Estimates [1]

Table K.5.1.3 contrasts the mean and percentile estimates of the SIF for the fish ingestion PDF for the Native American scenario with the fixed point estimate derived using the upper-bound values. The results show that the SIF derived using the upper-bound values lies above the 95th percentile of the SIF probability distribution. The mean of the SIF probability distribution was one order of magnitude lower than the fixed point estimate. This suggests that the Native American Scenario fish ingestion SIF derived using default parameters is an upper-bound estimate and may not be representative of the typical intake by a Native American resident.

Uncertainty in the Groundwater Volatile Organic Compound Inhalation Summary Intake Factor

The Native American scenario groundwater volatile organic compound (VOC) inhalation SIF was based on exposures over a 70-year duration to an individual residing onsite. The exposed individual was assumed to have an inhalation rate of 15 L/day (4 gal/day) 365 days/year (DOE 1996). The VOC inhalation SIF is expressed by the following equation:

Where:

SIF = Summary intake factor (liters)
IR = Inhalation rate (cubic meters/day)
EF = Exposure frequency (days/year)
ED = Exposure duration (years)
VF = Volatilization factor (liters/cubic meter)

The volatilization factor (VF) was used to approximate the quantity of water in indoor air based on the absolute humidity (Andelman 1990). This factor was used to account for activities such as showering, cooking, and time spent in a sweat lodge. The VF was assumed to be 0.1 for the purposes of this calculation (DOE 1996). The groundwater VOC inhalation SIF fixed point estimate using default parameters was 3.84E+04 L (1.01E+04 gal) (DOE 1996).

Indoor air inhalation rates have been shown to vary depending on the activity level of the exposed individual (Layton 1993). On average, inhalation rates for time spent indoors during showering have been shown to vary from a maximum value of 30 m^3/hr (1,060 ft^3/hr) to an average of 11 m^3/hr (390 ft^3/hr) to a minimum of 2 m^3/hr (71 ft^3/hr) (EPA 1989). For the purposes of this evaluation, a triangular distribution with these limits was used to describe the Native American scenario VOC inhalation SIF.

The exposure duration and exposure frequency parameters for the Native American scenario were assumed to follow distribution similar to those of populations in the rest of the United States. Israeli-Nelson (1992) showed that the time spent at a residence follows a lognormal distribution with a mean value of 4.55 years and a standard deviation of 8.68 years (Israeli-Nelson 1992). The exposure frequency for ingestion of drinking water was approximated using a triangular distribution with a maximum of 365 days/year, most probable value of 345 days/year, and a minimum of 180 days/year (Smith 1994).

Monte Carlo uncertainty and sensitivity analyses were performed on the groundwater VOC inhalation SIF. The sensitivity analysis indicated that the parameters that contributed the most to the uncertainty in the SIF as measured by rank order were exposure duration, inhalation rate, volatilization factor, and exposure frequency. The results of the Monte Carlo analysis are summarized in Table K.5.1.4.

Table K.5.1.4 Native American Scenario VOC Inhalation SIF Estimates [1]

Table K.5.1.4 contrasts the mean and percentile estimates of the PDF for the groundwater VOC inhalation SIF for the Native American scenario with the fixed-point estimate derived by using the upper-bound values. The results indicated that the SIF derived using the upper-bound values lies at approximately the 95th percentile of the SIF probability distribution. Furthermore, the mean of the SIF probability distribution function was approximately one-third the magnitude of fixed-point estimate. This suggests that the groundwater VOC inhalation SIF derived using default parameters is an upper-bound estimate.

K.5.1.4 Residential Farmer Scenario

The residential farmer scenario was based on a 30-year exposure of an individual residing onsite. The individual was assumed to be exposed to contaminated soil, air, surface, and groundwater, and homegrown fruits and vegetables 365 days per year. The evaluation for the residential scenario indicated that the site risk to a resident was driven by the drinking water ingestion exposure pathway. The exposed individual was assumed to ingest 2 L (0.5 gal) of contaminated water per day, 365 days per year for 30 years. The drinking water ingestion SIF may be expressed by the following equation:

Where:

SIF = Summary intake factor (L)
IR = Ingestion rate (L/day)
EF = Exposure frequency (day/year)
ED = Exposure duration (year)

The point estimate for the SIF for ingestion of drinking water was 2.2E+04 L (5.8E+03 gal) (DOE 1995). Drinking water ingestion rates were shown by Burmaster to following a lognormal distribution with a mean value of 1.12 L/day (0.3 gal/day) and a standard deviation of 1.63 L/day (0.43 gal/day) (Rosenberry-Burmaster 1993). Similarly, the time spent at a residence follows a lognormal distribution with a mean value of 4.55 years and a standard deviation of 8.68 years (Israeli-Nelson 1992). The exposure frequency for ingestion of drinking water was approximated using a triangular distribution with a maximum value of 365 days/year, most probable value of 345 days/year and minimum value of 180 days/year (Smith 1994).

A Monte Carlo uncertainty and sensitivity analysis was performed on the SIF for drinking water ingestion. The results of the sensitivity analysis indicated that parameters that most influence the SIF for drinking water ingestion were in rank order: ingestion rate, exposure duration, and exposure frequency. The results of the Monte Carlo-based analysis are summarized in Table K.5.1.5.

Table K.5.1.5 contrasts the PDF percentile estimates of the SIF for groundwater ingestion for the residential farmer scenario with the point estimate derived using the EPA upper-bound values. The results show that the point estimate lies above the 95th percentile of the SIF probability distribution. The mean of the SIF probability distribution was approximately one order of magnitude lower than the EPA point estimate. This result demonstrates that the drinking water SIF derived using EPA default parameters is an upper-bound estimate and may not be representative of the typical intake of any hypothetical future resident.

Table K.5.1.5 Residential Farmer Scenario Drinking Water Ingestion SIF Estimates [1]

K.5.1.5 Industrial Worker Scenario

The industrial exposure scenario was based on worker exposure over a 20-year duration. The scenario involved mainly indoor activities, although outdoor activities (e.g., soil contact) also were included. Latent cancer fatalities (LCFs) for this scenario were shown to result principally from the inhalation of radiological atmospheric emissions. The SIF for the inhalation exposure route may be expressed by the following equation:

Where:

SIF = Summary intake factor (m^3)
IR = Inhalation rate (m^3/day)
ED = Exposure duration (years)
EF = Exposure frequency (days/year)

The SIF using EPA default factors assumed that the air inhalation rate was 20 m^3 per day for a worker and external exposure occurred for 8 hours per day. Inhalation of radionuclides occurs 250 days per year and external exposure would occur 146 days per year. The point estimate SIF for inhalation of radionuclides was 1.0E+05 m^3 (3.5E+06 ft^3) (DOE 1995).

A Monte Carlo uncertainty and sensitivity analysis was conducted using the above algorithm for calculating the industrial worker SIF. The results of the sensitivity analysis indicated that parameters that most influence the industrial worker SIF were in rank order: exposure duration, inhalation rate, and exposure frequency. The results of the Monte Carlo-based analysis are summarized in Table K.5.1.6.

Table K.5.1.6 Industrial Worker Scenario Inhalation SIF Estimates [1]

Table K.5.1.6 contrasts the PDF percentile estimates of the air inhalation SIF distribution for the industrial worker scenario with the point estimate derived using the EPA upper-bound values. The results show that the point estimate is equal to the 95th percentile of the inhalation SIF probability distribution. The 50th percentile of the inhalation SIF probability distribution was one order of magnitude lower than the EPA point-estimate. This result demonstrates that the worker inhalation SIF derived using EPA default parameters is an upper bound estimate and may not be a realistic estimate of the true intake or exposure to an industrial worker at the Hanford Site.

K.5.1.6 Recreational Shoreline User and Recreational Land-User Scenarios

The recreational shoreline user scenario represented exposure to contamination in the Columbia River and shoreline from recreational swimming, boating, and other shoreline activities. The scenario involved mainly outdoor activities and would occur from exposure 14 days/year for 30 years.

The total adverse health impacts to a hypothetical future recreational shoreline user were expressed as the incremental lifetime cancer risk (ILCR) from the present to sometime in the future. The uncertainty associated with the adverse health effects predicted from this scenario can be attributed to the uncertainties in the source concentration, transport modeling, exposure parameters, and toxicological factors used to predict the total ILCR. However, the results of the risk analysis (Volume Three, Table D.5.1.2) indicated that the ILCR would be insignificant (i.e., less than 1E-10) for a period of 10,000 years. The uncertainties in the source concentration, and transport modeling would have to have had a combined uncertainty on the order of 1E+04 to 1E+06 to have a significant effect on the final result. This degree of conservatism is not likely to have been introduced into the final risk calculation.

The total adverse health impacts to a hypothetical future recreational land user scenario were expressed as total cancer incidence from the present to a time 10,000 years in the future. The uncertainties in the exposure factors alone have been shown for other scenarios (i.e., residential farmer) to be a least one order of magnitude too high when compared to the mean of the exposure term. Factoring this uncertainty into the final cancer risk predictions for the future recreational land user would result in mean cancer incidences at least one order of magnitude less than the predicted incidence rate. This conclusion seems justified given the fact that there was considerable uncertainty in the intermittent exposure terms used for this scenario.

K.5.1.7 Intruder Scenario

The potential consequences of intrusion into a Hanford Site solid waste burial ground at some time in the future were estimated by assuming a "post-drilling resident" scenario in which someone has a vegetable garden in the soil resulting from the drilling of a 30-cm (1-ft) diameter well. Furthermore, in order to represent the potential dose from all pathways via irrigation, a combination of farming and garden irrigation was used. In this scenario, a farm over the waste site was assumed to have 1 percent of the plant roots in the waste. One-fourth (25 percent) of the farmers vegetable intake and all (100 percent) of his meat and milk intake were assumed to be locally produced (i.e., contaminated). Furthermore, a well near the waste site was assumed to irrigate the vegetable garden. A more detailed description of the intruder scenario is presented in Volume Three, Section D.7.0. and in Rittman (Rittman 1994).

The results of the dose estimates for the intruder scenario (Rittman 1994) indicated that of the three principal routes of exposure (i.e., external, ingestion, and inhalation) the external would be the principal route of exposure followed by inhalation and ingestion. Thorium-232 (Th-232) was shown to be the radionuclide of concern (see Volume Three, Table D.7.3.1). The point estimate for the intruder scenario dose factor for Th-232 was 1.2E+04 mrem per year per curie exhumed. This point estimate was derived by assuming conservative upper-bound intake parameters. A Monte Carlo uncertainty and sensitivity analysis then was conducted on the algorithm used to calculate the intruder scenario effective dose factor (Rittman 1994). The sensitivity analysis indicated that parameters that contributed the most to the uncertainty in the intruder effective dose were in rank order: soil concentration, external exposure time, soil density, contamination depth, inhalation exposure time, and residential lot surface area. The results of the Monte Carlo analysis are summarized in Table K.5.1.7.

Table K.5.1.7 Intruder Scenario Dose Estimates [1]

Table K.5.1.7 contrasts the PDF percentile estimates of the dose estimates for the intruder scenario with the point estimate derived using the upper-bound values. The point estimate lies at approximately the 100th percentile of the dose probability distribution function. The mean of the intruder dose probability distribution function was approximately an order of magnitude lower than the point estimate. These results demonstrated that the dose estimates predicted for the intruder scenario by using default EPA exposure factors were conservative and could be an unrealistic estimate of the effective dose received by a hypothetical intruder.

Source terms from intrusion were probabilistic. The probability and consequences associated with the intruder scenario would be as follows: the intruder scenario in the TWRS EIS is the same as the intruder scenario in the Disposal of Hanford Defense High-Level, Transuranic, and Tank Wastes Final EIS, Sections R.3 and R.5. Both are based on Aaberg and Kennedy (Aaberg-Kennedy 1990). The Disposal of Hanford Defense High-Level, Transuranic, and Tank Wastes Final EIS conducted a comprehensive probability and consequence analysis of radionuclide release and transport after disposal as a result of human intrusion. The results of this study were applied directly to the TWRS EIS intruder scenario uncertainty analysis.

The existing estimated risk to the intruder was based on the consequences only. The basic advantage of a probabilistic approach is that the probabilities of events occurring and the consequences are both taken into account. This gives a broader perspective of the performance assessment than a consequence analysis alone.

The amount of waste exhumed was estimated for each aggregated area. Estimates of annual probabilities for drilling into a tank or capsule are given in Table K.5.1.8. Source terms (initial exhumed inventory) were estimated for each drilling for each alternative (Volume Three, Tables D.7.1.1 to D.7.1.6). The following equation was used for calculating the y^{th} percentile value of the accumulated release of constituent n from waste class w to the land surface due to drilling:

Where:

RQ_n = initial inventory (Ci) of radionuclide n in waste class w
T_{drill} = time of drilling (year) after the year 1995 (100 years)
A_W = surface area of waste class w (km^2)
A_{BH} = surface area of borehole (7.0E-08 km^2)
$I_W(y)$ = the y^{th} percentile value of the number of boreholes in waste class w

The term in the previous equation is the exhumed inventory as presented in Volume Three, Tables D.7.1.1 to D.7.1.6. Therefore, the y^{th} percentile value of the exhumed waste for each radionuclide and each alternative can be calculated as:

$$RQ_n\,[I_W(y)] = I_{exhumed} \cdot I_W(y)$$

The percentile values for each class of waste are presented in Table K.5.1.9. These values were estimated using the Poisson distribution.

Table K.5.1.8 Annual Probabilities of Drilling into the Waste and Waste Surface Area

Table K.5.1.9 Percentile Values of Number of Boreholes in Each Waste Class (in a 10,000-year period)

Secondary sources of uncertainty are the transport and accumulation of radionuclides in the food chain, exposure pathways, and dose conversion factors. The exposure pathway parameters are the most easily quantified of these sources. The expected ranges and selected values for the exposure pathway parameters for drilling and post drilling are shown in Table K.5.1.10.

K.5.1.8 Total Health Impacts for Post-Remediation Land Users

The total adverse health impacts to a hypothetical future land user were expressed as the total calculated cancer fatalities over a 10,000-year period. The cancer fatalities were calculated by first computing the total cancer risk for a given population then dividing by the dose to risk conversion factor for cancer incidence and cancer fatalities (ICRP 1991). As shown in Volume Three, Section D.5.14.1, the total cancer fatalities for a given time span may be computed by the following equation:

Table K.5.1.10 Selected Parameter for Intruder Scenario

Where:

F = Total cancer fatalities (persons)
A = Area corresponding to ILCR (km^2)
P = Population density (persons/km^2)
D = Duration of each generation (years)
T = Time span (thousand years)
ILCR = Incremental cancer risk for a given area
1.2 = Dose to risk conversion factor for cancer incidence and cancer fatalities

The total cancer fatalities for a given time span may be computed as shown in the example problem of Volume Three, Section D.5.14.1. Using the previous equation and the sample problem of Section D.5.14.1, the point estimate for total cancer fatalities (F) may be computed as follows:

The uncertainty associated with the total cancer fatalities to a post-remediation residential farmer may be estimated using the Monte Carlo approach. The previous equation assumed that both population density (P) and duration of each generation (D) were fixed values when in fact there would be considerable uncertainty associated with each of these parameters. The Monte Carlo approach assumed that population density (P) would be a triangular distribution with a maximum value of 5 persons per km^2, most probable value of 3 persons per km^2, and a minimum value of 1 person per km^2. The expected life span of a generation was represented as a lognormal distribution with mean of 75 years and standard deviation of 7.5 years (EPA 1989). The results of the Monte Carlo analysis are summarized in Table K.5.1.11.

Table K.5.1.11 Post-Remediation Land Users Fatality Estimates [1]

Table K.5.1.11 contrasts the percentile estimates of the post-remediation land users fatality estimates with the point estimate value derived using the EPA upper-bound values. The total fatalities derived using the upper-bound values were greater than the 95th percentile of the fatality probability distribution. The mean of the fatality probability distribution was approximately 56 percent of the point estimate.

A note of qualification is appropriate with regard to the long-term, post-remediation collective doses and risks presented in the EIS. The National Council on Radiation Protection (NCRP) (NCRP 1995) cautions that the application of the concept of collective dose as a means of estimating prospective risks to populations from potential radiation exposures is subject to practical limitations. A calculated collective dose may contain such large inherent uncertainties that it would be a poor indicator of risk and therefore should not be considered as a basis for decision. The NCRP notes that neither population size and characteristics nor environmental exposure pathways for most radioactive elements are predictable with any degree of confidence for more than a few generations into the future (NCRP 1995). The NCRP also cautions that the summation of trivial average risks over very large populations or time periods into a single value may produce a distorted image of risk that is completely out of perspective with risks accepted every day, both voluntarily and involuntarily. In many instances, the collective dose increases with increasing size of the exposed population, but the benefits and risks to individuals remain nearly constant. Population exposure pathways and other assumptions have been projected for this EIS out of 10,000 years using the best available data and considered judgment but clearly are subject to the considerable uncertainty suggested by the NCRP. Therefore, the collective dose projections presented in the EIS should not be considered an exact measure of the true (absolute) quantity of dose or risk for any alternative. However, they are useful for comparison of the relative risk of the alternatives because the parameters that contribute large uncertainties are constant across the alternatives.

Finally, the NCRP suggests that whenever the collective dose is smaller than the reciprocal of the relevant risk coefficient, the risk assessment should note that the most likely number of consequences (e.g., cancer deaths) is zero. For example, the most likely ILCR for a cumulative population dose of 1,000 person-rem would be zero because the reciprocal of the relevant risk factor of 5E-04 (i.e.,1/5E-04 = 2,000).

K.5.1.9 Total Health Impacts Along the Columbia River

This scenario was used to estimate the dose to a population of people exposed to contamination from the Columbia River. The contamination would enter the Columbia River as a result of groundwater flow into the river. Different contaminants would enter the groundwater and reach the Columbia River at varying times in the future. Transport of contaminants through the groundwater is described in detail in Volume Four, Appendix F.

Total cancer fatalities were calculated using factors that relate the number of fatal cancers to the curies of each contaminant released to the river. These factors were calculated using a computer program that estimated the time integral of collective dose over a period of up to 10,000 years for time variant radionuclide release to surface waters, such as rivers (DOE 1987). The results of the dose estimates for the Columbia River scenario indicated that of the three principal routes of exposure (i.e., external, ingestion, and inhalation), ingestion would be the principal route, followed by inhalation and external exposure. The Np-237 was shown to be the radionuclide of concern to hypothetical receptors along the Columbia River (Rittman 1994). The point estimate for the Columbia River scenario dose equivalent factor for Np-237 is 1.0E+04 person-rem. A Monte Carlo uncertainty and sensitivity analysis was conducted on the algorithm used to estimate the dose for the Columbia River scenario. The sensitivity analysis indicated that parameters that most influenced the equivalent dose were in order: root uptake factor, root ingestion rate, Columbia River flow rate, total population exposed, months per year of irrigation, and soil area density. The results of the Monte Carlo analysis are summarized in Table K.5.1.12.

Table K.5.1.12 contrasts the percentile estimates of the dose estimates for a hypothetical Columbia River receptor with the point estimate derived using the upper-bound values. The point estimate lies at approximately the 100th percentile of the probability distribution function. The mean of the Columbia River probability distribution was approximately one order of magnitude less than that of the point estimate. Again, these results suggested that the dose estimates predicted for the Columbia River scenario were upper-bound estimates. The typical dose to a receptor could be an order of magnitude less than that predicted by the fixed-point estimate.

Table K.5.1.12 Columbia River Scenario Dose Estimates [1]

K.5.2 REMEDIATION ROUTINE EXPOSURE

The range of possible unit dose factors for offsite receptors would primarily depend on individual consumption rates and environmental transport factors such as the soil-to-plant concentration ratio. Age-dependent variations were considered to have less effect because the generally higher internal dose factors for the lower age groups (ICRP 1975) were offset by the lower breathing and food consumption rates. Thus, age dependence was not expected to be as important as the factors mentioned.

To analyze the bounding range for the individual consumption rates, the standard maximum individual in GENII was considered to have the highest likely consumption rate. The lower end was taken to be the consumption rates used in recent low-level waste performance assessments at the Hanford Site (Kincaid et al. 1995; Wood et al. 1995). These were 25 percent of the average annual dietary intakes of garden produce and 50 percent of the average annual dietary intakes of meat, poultry, milk, and eggs. In the calculation of population dose, this variation disappeared in the population average consumption rates. Thus, for estimating the range of possible population unit dose factors, the only contributor was assumed to be the variation in agricultural transfer factors.

To analyze the bounding range for the various agricultural transfer factors, the values found in NUREG/CR-5512 (Kennedy-Strenge 1992) were used with scale factors. For the soil-to-plant concentration ratios, the scale factors were selected to be 0.1 and 10 to accommodate the large variation in the published values. The variation of the equilibrium transfer factors into animal products was taken to be 0.3 and 3, because there is more consistency in the reported values. To account for the smaller variation over population averages, these variations were reduced by a factor of 2. The food consumption rates (kg/year) from EPA and GENII are listed in Table K.5.2.1.

Scenario dose factors were computed using GENII Version 1.485 (Napier et al. 1988) with two exposure scenarios. The first was the air pathway chronic dose for the MEI at the site boundary. The normalized integrated exposure (Chi/Q) was set equal to 1 and unit activities of each nuclide of interest were used. The second exposure scenario was for the total population, again with a unit Chi/Q. The dose results are shown in Table K.5.2.2.

Table K.5.2.1 Food Consumption Rates (kg/year) for 25 Percent of EPA and for GENII

Table K.5.2.2 Dose Factor for the Offsite MEI and Population Using Best Estimates

Table K.5.2.2 compares the effect of changing food transfer factors from those currently in GENII to those in NUREG/CR-5512. The most significant change occurs for Tc-99, which would contribute little to the overall air pathway dose. Thus, for the TWRS comparisons, the two sets of food transfer factors can be considered the same.

Table K.5.2.3 shows the dose factors that resulted when the low consumption rates were combined with the low transfer factors, as well as when the high consumption rates were combined with the high transfer factors. The unit release dose factors for the offsite maximally-exposed individual (MEI) differed only in these two assumptions. The exposure times, average breathing rate, and other agricultural parameters were held constant.

Using the dose factors listed in Tables K.5.2.2 and K.5.2.3, the estimated dose factor range were reduced to a ratio of the low or high value divided by the expected value using the NUREG/CR-5512 transfer factors. These ratios are shown in Table K.5.2.4.

Table K.5.2.3 Dose Factors for the Offsite MEI and Population Using Adjusted Food Transfer Factors from NUREG/CR-5512

Table K.5.2.4 Ratios of Bounding [1] and Expected [2] Dose Factor

The above ratios could not be used to determine the bounding range of doses for mixtures of nuclides unless one nuclide gives nearly all the dose. For other cases, the doses must be computed for the mixture and then the bounding ratios can be calculated from the total dose. An example is given in Table K.5.2.5. From this table, the MEI dose factor ranged from 0.1 to 2.3 times the reported dose, while the offsite population dose ranged from 0.7 to 1.3 times the reported dose. These ratios were calculated by dividing the low or high dose value for each receptor by the best dose estimate.

These results show small uncertainties in the estimated dose calculations. The overall uncertainties associated with airborne transport, accumulation of constituents in food products, and dose conversion factors were not as significant as the source and release terms.

Table K.5.2.5 Comparison of Routine Dose Calculation for Mixtures of Nuclides

K.5.3 REMEDIATION ACCIDENTAL EXPOSURE

Radiological exposure to the receptor groups was based on the radiological activity concentrations in the source term. Activity concentrations for six composite inventories were used as the radiological source terms in the tank farms accident analyses. The bounding composite inventory bounds 100 percent of all the tank characterization sample data. The nominal inventory was a total tank farm average by volume based on the inventory of radioactive materials contained in the fuel from the single-pass reactors and N Reactor and transferred to the tank farms. GENII was used to generate a single unit liter dose (ULD) value for each composite source term. The bounding ULDs for the six composite inventories and the nominal ULD used in the accident analyses are presented in Table K.5.3.1. The greatest difference between bounding and nominal is the Aging Waste Facility (AWF) solids inventory with a ratio of 6.00E+02.

Table K.5.3.1 Accident Source Term Unit Liter Dose Values for Bounding and Nominal Scenarios

In Volume Four, Section E.15, analysis is presented regarding uncertainties associated with the accident analysis for the tank waste alternatives. For the operation accidents, uncertainties were associated with the inventory of waste in the tanks and the atmospheric conditions that would transport the waste released as a result of an accident. The tank waste inventory used in this EIS is presented in Volume Two, Appendix A along with uncertainties associated with the quality of the data. Because of this uncertainty, for tank farm accidents, a composite inventory was developed. This composite incorporated estimates of the historical tank contents, the results from prior individual tank analyses, and the results of recent tank characterization programs (Shire et al. 1995). This composite provided a bounding tank waste inventory for the accident analysis.

Atmospheric conditions would influence the dispersion of contaminants in air to potential receptors. The bounding case analyzed in the EIS used conservative atmospheric conditions (99.5th percentile). The uncertainty analysis compared the results of these bounding case conditions to typical atmospheric conditions (50th percentile).

There also were uncertainties associated with the analysis of consequences of an accident involving the transportation of vitrified HLW to the potential geologic repository under certain tank waste alternatives. The potential consequences would be influenced by the weight percent of HLW that would be mixed in the glass. The baseline analysis in the EIS assumed a 20 percent waste loading. However, waste loading could be as low as 15 percent or as high as 40 percent. Uncertainties associated with waste loading are discussed further in Volume Two, Section B.8. To address this uncertainty in Volume Four, Section E.15, the impacts of a transportation accident involving the baseline waste loading were compared to an accident involving vitrified glass with a 15 percent waste loading and with a 40 percent waste loading. In addition to the uncertainties associated with the accident analysis, a number of important assumptions influenced the results. These assumptions include the following:

- The offsite general public population for operation accidents was based on 1990 census data. While it is unlikely that the population would be constant throughout the operation phase of each alternative, the 1990 census provided a uniform basis for comparison of impacts among the alternatives.
- The onsite worker population for operation accidents was based on the 1995 Hanford Site work force. In the future, the Site work force would likely decline, resulting in proportionately lower impacts than presented in the EIS. However, use of the existing worker population provided a bounding analysis in terms of total impacts and provided a basis for uniform comparison of impacts among the alternatives.
- For transportation of HLW to a potential geologic repository, the accident scenarios were based on transportation of the waste from the Hanford Site to Yucca Mountain, Nevada by rail.
- For nonradiological occupational construction, operation, and transportation accidents, it was assumed that injuries, illnesses, and fatalities would occur at rates similar to historical rates for each activity.
- It was assumed that there would be no evacuation of Hanford Site personnel in the event of an accident. Emergency planning and evacuation programs are in place at the Hanford Site to mitigate potential consequences resulting from an accident.

The uncertainties in calculating the radiological doses and the toxicological exposures resulting from operation accidents included the tank inventory concentration and the atmospheric dispersion once the source term is in the air. A sample accident scenario is presented in Table K.5.3.2 to illustrate these uncertainties. The illustration shows the difference between the bounding and nominal parameters; the concentration of the inventory was a factor of 30; and the atmospheric dispersion coefficient was a factor of 12 for the MEI noninvolved worker, 30 for the noninvolved worker population, 22 for the MEI general public, and 15 for the general public population. For the noninvolved worker population, a bounding dose of 2.52E+03 person-rem was estimated. This was 3 orders of magnitude higher than the estimated nominal dose of 2.89E+00 person-rem.

Table K.5.3.2 Table K.5.3.2 Uncertainty Evaluation for Mispositioned Jumper - Common to All Tank Alternatives

The main uncertainty associated with estimating the radiological doses resulting from accidents while transporting vitrified HLW to a potential geologic repository was the weight percent of the waste that could be mixed with the glass matrix. A sample accident scenario is presented in Table K.5.3.3 to illustrate these uncertainties. The baseline analysis used in the EIS assumed a 20 percent loading. A range from 15 to 40 weight percent was used in the uncertainty evaluation in Table K.5.3.3. The population dose was calculated by RADTRAN 4 (Neuhauser-Kanipe 1992) and was based on the worst credible accident parameters in the urban population zone.

Table K.5.3.3 Uncertainty Evaluation for HLW Glass Transport Accident - Ex Situ Intermediate Separations

Alternative

The accident initiator frequencies were established using currently accepted sources such as natural phenomena statistics for the Hanford Site or recent analysis of the initiators from safety assessment reports. The frequencies of these accidents were presented as estimates and were provided as an aid in screening accident scenarios. Only 10-fold differences in frequencies would be significant. For example, accident frequencies of 1E-6 and 5E-05 should not be considered significantly different.

The nonradiological injuries and fatalities resulting from construction and operation accidents were based on incidence rates in the occupational injuries summary report (DOE 1994j). The transportation injuries and fatalities from trucks and trains were based on incidence rates in statistics compiled by the U.S. Department of Transportation (Rao et al. 1982). Injuries and fatalities resulting from employee vehicle accidents were based on incidence rates in the Washington State Highway Accident Report (WSDT 1993). Because these are widely accepted, statistically based incidence rates, there was no attempt to evaluate the uncertainties.

K.6.0 UNCERTAINTY IN HUMAN HEALTH RISK

Human health risk assessment results are conditional estimates that depend on the assumptions made to account for uncertainties in biological processes or a lack of information on source data, transport, or receptor behavior. It is important to recognize these uncertainties to place the risk estimates in proper perspective. The uncertainties associated with the TWRS EIS risk estimates include parameters involved in the models used and historical data on worker risks and accidents. Volume Three, Appendix D presents some parameter uncertainties associated with remediation risk (Section D.4.14), anticipated post-remediation risk (Section D.5.14), ecological risk (Section D.6.5), and intruder risk (Section D.7.5), which are briefly discussed as follows.

To estimate risk, information must be available on dose-response relationships, which define the biological response from exposure to a contaminant. Although human epidemiological data are used for developing radiological and nonradiological chemical dose-response models, this information also is developed in laboratory tests using animals exposed to relatively high doses. Therefore, uncertainty is inherent in dose-response relationships, including extrapolating from effects in animals at high doses to potential effects in humans that most often are exposed at much lower doses.

Another important component of risk assessment is estimating exposure concentrations. Uncertainties associated with this component include estimating releases of contaminants from emission sources to different environmental media such as groundwater, soil, air, and surface water, the transport and transformation of contaminants in these media, and the pathway, frequency, and duration by which humans contact the contaminants.

The risk associated with the release of radionuclides or chemicals to ambient environmental media during routine operations was estimated using models. The risk estimates determined by these models have a greater uncertainty than those based on historical data. However, it is reasonable to assume that releases would occur on a routine basis over the operational lifetime of the facility. The risk estimates for post-remediation and intruder scenarios are associated with more uncertainty than facility routine operation risk and involve uncertainties associated with the hypothetical land use and intrusion in addition to modeling. Finally, the MEI risk estimates generally involve a greater level of uncertainty than population risk estimates.

K.6.1 POST-REMEDIATION LAND-USER RISK

The uncertainty analyses for post-remediation risk assessment were based on the Hanford Site Risk Assessment Methodology (HSRAM) uncertainty analysis. The carcinogenic and noncarcinogenic risks presented in the post-remediation risk evaluation were estimates based on multiple assumptions about exposures, toxicity, and other variables. Therefore, discussion of uncertainty was provided for this risk assessment. The uncertainties are inherent (e.g., toxicity values, default exposure parameters) or specific (e.g., data evaluation, contaminant identification) in the risk assessment process. Specific considerations in evaluating uncertainty were Site-specific factors, exposure assessment factors, toxicity assessment factors, and risk characterization factors, which are discussed as follows.

K.6.1.1 Site-Specific Uncertainty Factors

Uncertainty related to the source inventory, Site contamination, availability of information on Site-specific environmental conditions (e.g., climate, geology, and hydrogeology), and uncertainties in model application to the Site were important in assessment of risk associated with the Site. These uncertainties are addressed in Appendices A, B, and F.

K.6.1.2 Exposure Assessment Uncertainty Factors

Exposure assessment requires multiple assumptions that can affect the outcome of a risk assessment. Key factors contributing to uncertainty in the exposure assessment included the following:

- Identification of land use;
- Likelihood of future land use actually occurring;
- Model assumptions that affect exposure point concentrations;
- Use of standard default parameters (e.g., upper 95th percentile values for intake/contact rates, exposure frequency, and exposure duration);
- Uncertainty related to biotransfer factors;
- Uncertainty related to production and distribution of food; and
- Uncertainty related to lifestyle and diet of specific or referenced individuals.

K.6.1.3 Toxicity Assessment Uncertainty Factors

A high degree of uncertainty was associated with data used to derive toxicity values and resulted in less confidence in assessment of risk associated with exposure to a substance. Sources of uncertainty associated with published toxicity values include:

- Use of dose-response information from effects observed at high doses to predict effects at the low levels expected in the environment;
- Use of data from short-term exposure studies to extrapolate to long-term exposure or vice-versa;
- Use of data from animal studies to predict human effects; and
- Use of data from homogenous animal populations or healthy human populations to predict effects in the general population.

K.6.1.4 Risk Characterization Uncertainty Factors

The summation of cancer risk across pathways or for multiple pathways would result in more conservative risks. This is because the slope factor for each chemical carcinogen is an upper 95th percentile estimate and such probability distributions are not strictly additive. The risk values calculated for the post-remediation scenario in the TWRS EIS were a conservative bounding estimate. The uncertainty in the risk values for certain receptors would increase as the time in the future increased. Less uncertainty would be associated with the risk values at 300 years than the risk estimates at 500, 2,500, 5,000, and 10,000 years.

The best approach to more fully characterize the uncertainty would be to conduct a probabilistic risk assessment from the start of the evaluation. A probabilistic assessment uses the range of variation in contaminant information, exposure parameters, and toxicity data to provide a risk distribution curve. This appendix examines the effect of variations on these parameters on the risk estimates to provide a better understanding of the uncertainties.

K.6.2 POST-REMEDIATION INTRUDER RISK

The greatest uncertainty in calculating the intruder risk was associated with the source data. Source terms were based on the estimated inventory and an average tank within the eight aggregated tank farms of the 200 Areas. Additional information regarding the source term would decrease the uncertainty in the risk estimate.

The relative uncertainty associated with the dose conversion factor was not as important as the source data, source terms, and exposure pathway parameters. The GENII computer code was used for the intruder dose calculation. GENII used the dosimetry model recommended by the International Commission on Radiation Protection (ICRP), in ICRP Publication 26 (ICRP 1977) and ICRP Publication 30 (ICRP 1979-1982), with updates from ICRP Publication 48 (ICRP 1986). The dose conversion factors used were equivalent to those currently recommended by the (DOE 1988). External dose factors were equivalent to Kocher (Kocher 1981; ORNL 1981). The overall uncertainty associated with risk in respect to GENII is discussed in Volume Three, Section D.4.14.

K.6.3 REMEDIATION ROUTINE RISK

By far the greatest uncertainty in the routine remediation risk was associated with the source data, which were based on the estimated inventory and source terms (i.e., the amount of chemicals and radionuclides released into the environment). The uncertainties associated with the source and source terms are discussed in Volume Two, Appendices A and B. Other contributors to the routine risk uncertainty were the airborne transport of the released chemicals and radionuclides, accumulation of contaminants in food products, production and distribution of food products, and lifestyle and diet of specific individuals, food consumption rates, and dose conversion factors which are discussed in this section.

Routine chemical emissions from the tank farm during remediation were based on existing tank farm emissions data (Jacobs 1996). Operational emissions from the tank farm, such as would occur while retrieving waste from tanks and gravel-filling the tanks, were appropriately scaled for potential increased emission rates during remediation.

The hazard index (HI) approach conservatively assumed that the noncarcinogenic health effects were additive for all chemicals (i.e., all chemicals would have the same mechanism of action and affect the same target organ). The HI is the sum of the hazard quotients (estimated intake/reference dose) for all chemicals. A HI greater than or equal to 1.0 indicates potential adverse health effects in the population of concern. Conversely, a HI less than 1.0 suggests that adverse health effects would be unlikely.

Carcinogenic risks were assumed to be additive. Consequently, the total ILCR is the sum of individual chemical cancer risks from each emission source for each alternative analyzed. Regulatory agencies have defined an acceptable level of risk to be between 1 in 10,000 (1.0E-04) and 1 in 1,000,000 (1.0E-06), with 1.0E-06 being the point of departure and referred to as de minimis (below which there is minimal concern) risk. For the purpose of this EIS, a risk below 1.0E-06 was considered low, and a risk greater than 1.0E-04 was considered high.

K.6.4 REMEDIATION ACCIDENT RISK

The objective of this section is to summarize the results of the Monte Carlo uncertainty and sensitivity analyses of the LCF predictions associated with the potential accidental release of contaminants from each TWRS EIS remedial alternative.

A detailed description of the general methodology used in the Monte Carlo approach is presented in Section K.5.0. The methodology used to estimate the uncertainty in the LCF predictions was similar to that used to predict the uncertainty in the human health exposure factors (see Section K.5.0). In this approach, the variables used to predict the LCF were separated into variables which can be described as PDFs and those having constant or fixed point estimates. A computer simulation was then run in order to produce a PDF for LCF. The results of the computer simulation were then compared to the results of the fixed point estimate. The equation used to predict LCF from an accidental release is:

Where:

LCF = latent cancer fatality
Chi/Q = atmospheric dispersion coefficient (second/m^3)
V = release volume (rem/liter)
IR = inhalation rate (m^3/second)
ULD = unit liter dose (committed effective dose equivalent/liter)
C = conversion factor (LCFs/rem)

The Monte Carlo analysis described each of the variables in the above equation (i.e., Chi/Q, V, IR, ULD and C) as PDFs and not as a single value.

K.6.4.1 Accident Release Scenarios

This uncertainty analysis evaluated the consequences to four receptors as a result of the spray release accident scenario presented in Volume Four, Appendix E:

- MEI noninvolved worker;
- Noninvolved worker population;
- MEI general population; and
- General public population.

The radiological dose to a receptor would depend on the receptors location relative to the point of release of the radioactive material. Doses for a MEI and population dose were computed for each receptor (noninvolved worker and general public). Noninvolved workers would be onsite workers not involved in the proposed action. The general public would be people located off the Hanford Site. The MEI for each of these receptor categories would be a single individual assumed to receive the highest exposure in the category. Volume Four, Appendix E of this report contains a more detailed description of the receptors associated with each accidental release scenario.

K.6.4.2 Monte Carlo Uncertainty Analysis

The PDFs for the variables in the equation used to calculate LCF were assumed to be triangular distributions (Finley et al. 1994). Triangular distributions can be viewed as conservative characterizations of truncated normal or lognormal distributions. The triangular distribution was conservative in that it resulted in more frequent selection of values in the extremes of the factor's distribution.

The inhalation rate triangular PDF was assumed to have a minimum value of 6.9E-05 m^3/s (6 m^3/day), mean value of 2.1E-04 m^3/s (18.9 m^3/day), and maximum value of 3.7E-04 m^3/s (32 m^3/day) based on worker ventilation rates under light activity levels (EPA 1985).

The remaining variables in the equation for calculating LCF were also assumed to have a triangular PDF. The values were chosen to correspond to conditions associated with a nominal accidental release value as well as an upper bounding value for accidental release. A more detailed description of the accidental release scenarios and the rationale for the selection of the nominal and bounding values is presented in Section K.6.5.

A Monte Carlo analysis was conducted based on the above algorithm for calculating the LCF. The sensitivity analysis indicated that the parameters which contributed the most to the uncertainty in the LCF were as measured by rank correlation: the unit limit dose, the atmospheric dispersion coefficient, the release volume, the inhalation rate, and the conversion factor. The detailed results of the Monte Carlo analysis are presented in Attachment 1 and are summarized in Table K.6.4.1.

Table K.6.4.1 contrasts the mean and percentile estimates of the LCF distributions for the four accidental release scenarios with the fixed point estimate derived using the upper-bound values. The results show that the LCF derived using the upper-bound values is in all cases greater than the 100th percentile of the LCF PDF. The mean of the LCF PDF was approximately one order of magnitude less than the upper-bound fixed point estimate. These results demonstrate that the predicted LCF estimates would be upper bound estimates of cancer probability and/or fatality rates. The true probability of contracting cancer or fatalities as a result of cancer could actually be much less than the predicted value.

K.6.5 ANALYSIS OF NOMINAL VERSUS BOUNDING RISK ESTIMATES

The bounding risk estimates in the TWRS EIS used a series of conservative assumptions about source and release terms, environmental transport parameters, and the effects of a given exposure on cancer risk and noncancer health effects to account for the uncertainties involved in the alternatives. This section analyses the effect of using less conservative values for several of the source term, release term, and environmental transport assumptions on the risk estimates. No change was made in the SIFs used to estimate the risk from each exposure.

Based upon available data, the assumption for the distribution coefficient (K_d) for Np-237, a major contributor to the groundwater risks, was changed from zero, which implies that Np would move at the same rate as water, to 1.0, which implies that interaction with the soil would slow its movement to and through the aquifer. For the ex situ alternatives, assumptions about tank residuals were changed, as described in the following sections.

Table K.6.4.1 Comparison of Monte Carlo-Based and Fixed Point Estimates

K.6.5.1 Tank Residuals Nominal Case

A nominal case retrieval release and residual tank inventory was developed to assess the impacts that would result from nominal assumptions for tank releases during retrieval and the residual waste left in the tanks following retrieval. Details are presented in Volume Two, Appendix B. The nominal release inventory was developed by assuming that the waste would be diluted by one-third by adding liquids for sluicing during retrieval. Possible dilution ratios that would be used during waste retrieval ranged from 3:1 to 10:1. Thus, the dilution factor of one-third assumed for the nominal case was a conservative assumption. These dilution ratios represent the amount of liquid required to mobilize the waste solids and would be made of existing tank liquids and water additions. The nominal case retrieval release volume was assumed to be 15,000 L (4,000 gal) from each SST, and the contaminant concentrations were assumed to be two-thirds of the bounding case. The average volume of waste released from each SST during retrieval was not reduced for the nominal case, because insufficient information was available to support a lower average release volume. The volume released would depend on the ability to detect a leak and take corrective action.

The nominal tank residual inventory was developed by modifying the bounding tank residual inventory to reduce the mobile constituents of concern based on solubility. The mobile constituents of concern were evaluated because of their contribution to post-remediation risk. The isotopes C-14, Tc-99, and I-129 were reduced to the nominal case residual inventory to 10 percent of the bounding residual inventory. This was based on the assumption that 90 percent of the residual inventory of these isotopes would be soluble in the retrieval liquids and would be retrieved from the tanks for ex situ treatment. Typical sludge wash factors, representing the water solubility of these isotopes, were as high as 99 percent. The nominal case residual was limited to 90 percent to account for conditions in which the scale and hardened sludges would not see the sluicing liquid during retrieval. Table K.6.5.1 shows the nominal and bounding residual inventories for select mobile constituents.

Table K.6.5.1 Tank Residual Inventory, Curies

K.6.5.2 Nominal vs. Bounding Risk Results

The ILCR and HI results for the nominal and bounding cases are presented in Volume One, Table 5.11.7. The overall effect of the changes in the nominal case was to reduce the estimated risks. The size of the effect would vary with the exposure scenario, the alternative, and the future time examined (Volume One, Table 5.11.7). For some scenarios, for some points in time, the nominal case risks were higher than those for the bounding case. For example, the No Action alternative showed higher risks for the nominal than the bounding case for all scenarios at 2,500 years. This occurred because one of the key assumptions, decreasing the mobility of Np-237, caused the exposure to Np in groundwater to be delayed, but did not change its ultimate impact on the risk. In the bounding case, the risk from Np occurred early, because the Np was assumed to move quickly, and then decreased as the Np was removed by attenuation and ultimate loss to the Columbia River. Thus, relaxing a conservative assumption about contaminant mobility could have more effect on the timing than on the degree of risk. Nonetheless, Volume One, Table 5.11.8 demonstrates that the total cancer incidence over the 10,000-year period of interest is decreased in the nominal case.

K.7.0 NOMINAL CASE ANALYSIS FOR EX SITU INTERMEDIATE SEPARATION ALTERNATIVE

This section describes the results of the nominal case risk analysis for the Ex Situ Intermediate Separation alternative. The primary changes in the nominal, compared to the bounding case, were that the distribution coefficient (K_d) for Np-237, a major contributor to the groundwater risk, was assumed to be 1.0 rather than zero, which slows its movement through interaction with the soils. In addition, the residual inventory of isotopes C-14, Tc-99, and I-129 were reduced to 10 percent of the bounding residual inventory. These changes are described in more detail in Section K.6.5. The inventory of contaminants assumed to be released during retrieval for the nominal case analysis is presented in Tables K.7.0.1 and K.7.0.2. Differences from the bounding case are shown in bold.

Table K.7.0.1 Nominal Case Inventory of Contaminants Released During Retrieval for the Ex Situ Intermediate Separations Alternative

Table K.7.0.2 Inventory of Contaminants for the Low-Activity Waste Vaults Ex Situ Intermediate Separations Alternative

Atmospheric releases during remediation may be chronic or acute. A nominal case was analyzed only for the acute (accident) case, because risks for the chronic bounding case were already very low.

K.7.1 EX SITU INTERMEDIATE SEPARATIONS ALTERNATIVE EXPOSURE ASSESSMENT

Uncertainties in the Ex Situ Intermediate Separations alternative human health exposure assessment can be divided into two parts. The first part discusses the uncertainties associated with the exposure parameters used in the post remediation land use scenarios. The second part discusses the uncertainties associated with the accidental release scenarios. In both cases, a Monte Carlo approach was used to evaluate both the uncertainty in the exposure assessment and to establish the parameters which contribute the most to the uncertainty in the exposure assessment (i.e., sensitivity analysis).

In the Monte Carlo analysis, PDFs were used to represent the range of values of a given parameter. The Crystal Ball computer software was then used to simulate a large number of realizations of the set of random variables in each model. This computation was repeated a large number of times to produce complete PDFs of the output function. Statistical summaries of the results were then plotted to interpret the data.

K.7.2 POST-REMEDIATION LAND-USE SCENARIOS

The results of the uncertainty analysis of exposure parameters for the post-remediation land-use scenarios in the Ex Situ Intermediate Separations alternative are summarized in Table K.7.2.1. The mean or nominal value of the Monte Carlo result was computed and compared to the bounding or fixed-point estimate of the same function. The nominal (Monte Carlo) results were generally approximately one order of magnitude less than the bounding estimates. This result supports the statement that the bounding value used in the exposure assessment in the EIS is an upper bound estimate.

The ILCR for the nominal and bounding estimates are provided in Table K.7.2.2. These risk estimates reflected the changes in the source and transport assumptions only. They do not incorporate the Monte Carlo estimates of variation in exposure parameters. The changes in source and transport assumptions for the nominal case decreased the ILCR by one to two orders of magnitude for most of the exposure scenario - future time combinations considered (Table K.7.2.2). These risk probability differences decreased the total accumulative cancer risk incidence by approximately an order of magnitude over the 10,000-year period of analysis. Although using less conservative assumptions for the bounding case altered the distribution of the risk through time for some alternatives, especially No Action (see Section K.6.5); for Ex Situ Intermediate Separation, the two cases followed the same general pattern, with the nominal case covering a smaller area, consistent with its lower accumulative risk (Figure K.7.2.1). The spatial pattern of risk onsite was generally similar in the two cases, as illustrated for the residential farmer scenario in Figures K.7.2.2, K.7.2.3, and K.7.2.4. At 2,500 years, the nominal case risk would be confined to the 200 East Area (Figure K.7.2.2), but at 5,000 and 10,000 years, the spatial distributions of the bounding and nominal cases were similar. The bounding case risk at 5,000 years had a higher risk area between 200 West and 200 East Areas, and occupied more area to the north and west (Figure K.7.2.3), but at 10,000 years, the areas for the two cases were essentially identical (Figure K.7.2.4).

K.7.3 ACCIDENTAL RELEASE SCENARIOS

A Monte Carlo uncertainty and sensitivity analysis was also conducted on the parameters used to compute LCFs or the probability of contracting cancer as a result of an accidental air releases associated with the remedial actions. The sensitivity analysis indicated that the parameters which contribute the most to the uncertainty in the LCF for the accidental release scenarios were, as measured by rank correlation: the ULD, the atmospheric dispersion coefficient (Chi/Q), the release volume, the inhalation rate, and the LCF conversion factor. Table K.7.2.1 compares the mean value of the LCF distributions for the four accidental release scenarios with the bounding estimate derived using upper-bound exposure factors. The results indicated that the LCFs predicted using the upper-bound values were in all cases one to two orders of magnitude greater than the mean of the Monte Carlo result. These results demonstrated that the predicted LCF estimates were upper bound estimates of cancer probability and/or fatality rates. The true probability of contracting cancer or fatalities resulting from cancer could actually be much less than the predicted value.

K.7.4 EFFECT OF ASSUMPTIONS ABOUT GROUNDWATER FLOW AND DIRECTION

As described in Section K.4.2.1, Future Groundwater Flow Direction, the groundwater modeling and risk assessment in the EIS assumed groundwater levels equivalent to those recorded in December 1979. The appropriateness of these data as a basis for impact analysis was tested quantitatively by running the model and calculating consequent risks for the Ex Situ Intermediate Separations Alternative using the same assumptions as in the bounding case analysis except that there was no water inflow from site waste water disposal to the vadose zone. This scenario was called the no mound case.

The effects of changing the assumptions for the Ex Situ Intermediate Separations alternative are illustrated for the residential farmer scenario in Figures K.7.4.1 through K.7.4.3. These changes eliminated the future risk north and west of the 200 Areas, consistent with the similar changes in groundwater flow, described in Section K.4.2.1 and Volume Four, Appendix F. However, the total risk increased in the no mound case (Table K.7.4.1). This effect was most pronounced at 5,000 years, when the risk for the bounding case was spread over a long southeast to northwest diagonal across the site, with a higher risk area between 200 West and East Areas (Figure K.7.4.2). The no mound case risk at 5,000 years was confined to a band running east from the Central Plateau, and most of the risk above 1.0E-06 was within the higher isopleth, above 1.0E-04 (Figure K.7.4.2, Table K.7.4.1). At 10,000 years, the areas of risk were comparable in the two cases, although the no mound risk occupied a smaller area with a higher risk level than the bounding case (Figure K.7.4.3, Table K.7.4.1). The total estimated cancer incidence over the 10,000 year period of interest was approximately four times higher in the no mound case than in the case used in the EIS (Table K.7.4.1).

The predicted flow field for this scenario tended to have a more pronounced west to east flow direction with similar gradient magnitude, compared to the December 1979 flow field on which the impact assessments were based. This resulted in a smaller groundwater contaminant plume. Figures K.7.4.1 through K.7.4.3 illustrate the risk that would be associated with the bounding case and no mound case.

Table K.7.4.1 Areas of Risk Contours and Total Concern Incidence, Bounding and No Mound Cases

Figure K.7.4.1 Ex Situ Intermediate Separations Alternative, Residential Farmer Scenario, Post Remediation Risk from Tank Residuals and LAW Vaults at 2,500 Years from Present

Figure K.7.4.2 Ex Situ Intermediate Separations Alternative, Residential Farmer Scenario, Post Remediation Risk from Tank Residuals and LAW Vaults at 5,000 Years from Present

Figure K.7.4.3 Ex Situ Intermediate Separations Alternative, Residential Farmer Scenario, Post Remediation Risk from Tank Residuals and LAW Vaults at 10,000 Years from Present

Generally, a smaller contaminant plume would translate to higher contaminant concentrations and greater risk; however, the small plume would translate into few people being exposed. This effect would be partially offset by the longer vadose zone travel time and contaminant dispersion within the vadose zone.

K.8.0 ECOLOGICAL RISK UNCERTAINTY

This section provides a qualitative discussion of the uncertainties in the ERA. The ERA for this EIS used a screening level methodology to estimate potential radiological and chemical hazards to a suite of representative terrestrial receptors: the Great Basin pocket mouse, coyote, mule deer, red-tailed hawk, and loggerhead shrike (Volume Three, Section D.6). Pathways considered for the No Action alternative were food and water ingestion (all receptors except the mouse, which was assumed to obtain all water from metabolic sources), incidental soil ingestion (mouse and mule deer, coincident with consumption of vegetation), inhalation of routine releases (all), and direct external exposure (mouse, while in a burrow). Potential hazards to aquatic organisms were evaluated using the CRITRII program developed at the Pacific Northwest National Laboratory.

K.8.1 SOURCE TERMS

The source terms used for the ERA were the same as those used for the human health risk assessment. For the No Action alternative, the source terms were the inventory in the tanks for direct contact and food chain uptake, routine releases for air inhalation, and groundwater reaching the Columbia River in the future for water ingestion. Uncertainties in the source terms are described in Section K.3. The estimated ecological risks were directly proportional to the source contaminant concentrations, and uncertainty about these terms was considered relatively high. Therefore, the source terms were considered likely major contributors to the uncertainty in the ecological risk estimates. However, for the pathways involving direct exposure to stored wastes, radionuclide concentrations would have to have been overestimated by a factor of at least 10,000 for the "true" radiation doses to approach the 0.1 rad/day benchmark recommended by International Atomic Energy Agency (IAEA1992) for protection of terrestrial organisms, since most of the estimated doses were greater than 1,000 rad/day (Volume Three, Table D.6.4.1). Chemical concentrations would have to have been overestimated by a factor of 10 to 1,000 for the true HI to approach the benchmark value of 1.0, since most of the estimated HIs were between 10 and 1,000. If the inventories used for the existing risk estimates were underestimates, the corresponding true risks would be even greater than stated. Therefore, although the source terms were probably important contributors to the uncertainty in the absolute values of the risk estimates, it is not likely that better or more data would alter the conclusion that direct contact with the waste, either externally or through food chain uptake, would be very hazardous to ecological receptors.

Similar but converse arguments would apply to the estimates of inhalation and groundwater ingestion pathway risks to ecological receptors under the No Action alternative. Estimated radiation doses from these two pathways were very low compared with the two benchmarks used [0.1 rad/day for terrestrial organisms and 1.0 rad/day for aquatic organisms (IAEA 1992, NCRP 1991)] (Volume Three, Tables D.6.4.2, D.6.4.3, and D.6.4.6). The true radionuclide concentrations in air and water would have to be higher than those estimated by at least a factor of 10,000 for the maximum estimated doses to approach the lower of the two benchmarks of concern (0.1 rad/day). It is therefore unlikely that better estimates would alter the conclusion in the EIS that inhalation and groundwater ingestion would not be important sources of ecological risk under the No Action alternative. It is possible that more refined estimates of maximum future chemical concentrations in groundwater, assuming those estimates were 10-fold higher than the existing ones, could indicate potential chemical hazards to wildlife (Volume Three, Table D.6.4.5). This discussion would apply also to the estimated radiation doses resulting from inhalation of routine releases for the remediation alternatives. The true release terms would have to be higher than the existing estimates by several orders of magnitude for the estimated doses to approach the 0.1 rad/day benchmark of concern (Volume Three, Tables D.6.4.8 trough D.4.6.9). The exceptions would be the Ex Situ Intermediate Separation/Phased Implementation and the Ex Situ No Separation alternatives. The maximum radiation doses estimated for these two alternatives would exceed the 0.1 rad/day benchmark using the existing release estimates, and the real values would have to be 10- to 100-fold lower for the maximum radiation doses to fall below the level of concern. However, the minimum radiation doses for these two alternatives were approximately 100,000-fold lower than the maximum, supporting the claim that the existing dose values would be upper bound estimates.

K.8.2 ORGANISM VARIABLES

A number of species-specific variables contributed to the uncertainty in the ecological risk estimates: food, water, and soil ingestion rates; inhalation rates; body weights; home ranges; and the effective radius for absorption of energy from radioactive decay. Risk estimates for any given pathway are directly proportional to the associated contaminant intake rate. For example, a 10-fold difference in a food ingestion rate would produce a 10-fold difference in the estimated radiation dose or chemical HI. Therefore, the risk estimates would be expected to be sensitive to errors in the intake rates. However, as discussed in Section K.8.1, most of the risk estimates would need to be wrong by several orders of magnitude for the high values to fall below levels of concern or for the low values to exceed them. Errors of this size were considered unlikely for food ingestion rates, which were based on direct measures of various types (see sources for Volume Three, Table D.6.2.1). The exception would be the food ingestion rate for the loggerhead shrike, which was estimated from body weight using an empirical equation (Volume Three, Table D.6.2.1). Water and soil ingestion rates and inhalation rates were all estimated from body weight (water ingestion and inhalation) or dry matter intake (soil ingestion). Potential errors in these variables were likely greater than those for food ingestion, and the resulting risk estimates for the water and soil ingestion and the inhalation pathways could have a greater level of uncertainty than those for food ingestion. However, the food ingestion pathway has an additional source of uncertainty, biological transfer factors in the food chain (discussed in the following paragraphs), which the other pathways do not share.

Risk estimates for any given pathway would typically be inversely proportional to body weight, since body weight appears in the denominator of the equations for estimating intake of radionuclides or chemicals (Volume Three, Appendix D). However, as noted above, water ingestion rates and inhalation rates were estimated from empirical equations that are a function of body weight. This causes weight to appear in both the numerator and denominator of the intake equations, reducing its overall effect on the risk estimate. For example, a simple equation for the intake of a chemical by water ingestion is:

1)

Where:

I_i = Intake rate of the i_{th} contaminant, mg kg^{-1} day^{-1}

C_i = Contaminant concentration in water, mg L^{-1}

IR = Ingestion rate of water, L day^{-1}
BW = Body weight, kg
FI = Fraction ingested from contaminated source, unitless

Here, the intake rate of a contaminant in water would be inversely proportional to the body weight, if the water ingestion rate remained constant. However, larger animals generally drink more water than smaller animals (on a per organism basis), so that as the denominator, body weight, increases, IR in the numerator also increases. In the TWRS EIS, this was explicitly the case, because IR was estimated from body weight using empirical equations. For example, the equation used to estimate water ingestion by the coyote and mule deer is:

2)

Where:

IR = Ingestion rate of water, L day^{-1}
BW = Body weight, kg

The equation used to estimate inhalation by the mouse, coyote, and mule deer is:

3)

Where:

IR = Inhalation rate, m^3 day^{-1}
BW = Body weight, kg

The overall effect of using these equations is to reduce the potential effect of body weight variability on the water ingestion and inhalation risk estimates and on the uncertainty in the estimates. In addition, in parallel with the previous discussions of source terms and intake rates, the body weight values would need to be wrong by orders of magnitude for the high risk values to fall below levels of concern or for the low values to exceed them. Errors of this size were considered unlikely, because the body weights were based on reported measured values of real organisms, and the body weights of adult mammals and birds do not vary by orders of magnitude within species.

Risk estimates in this ERA were also inversely proportional to the estimated home range, except that home ranges equal to or less than 100 hectares (ha) (250 acres [ac]), the unit cell size used for the risk assessment (see Volume Three, Appendix D), all have the same effect on the risk estimate. That is, FI, the fraction of exposure to a contaminated source (see Equation 1 above), was set equal to the ratio of the cell size and the home range. For example, the coyote home range of 300 ha (750 ac) (Volume Three, Table D.6.2.1) results in an FI of (100/302) equals 0.33. Above a home range of 100 ha (250 ac), exposure would be directly proportional to home range size. Below this, all species have the limiting FI of 1.0. For example, the mouse and loggerhead shrike have home ranges of 0.09 and 10 ha (0.22 and 25 ac), respectively (Volume Three, Appendix D), but both have an FI of 1.0. The consequence is that potential variability or errors in the estimated home ranges would have different effects on different species risks. A 1,000-fold error in the mouse home range (i.e., the real value is 90 ha [220 ac]) would not affect the mouse risk estimates, because the FI would still equal 1.0. However, any error or variability in the home ranges for the coyote, mule deer, or hawk, with estimated home ranges of 300, 1,200, and 222 ha, (750, 3,000 and 540 ac) respectively, would have a proportional effect on the risk estimates. Errors of 10-fold in estimates of home range would not be unlikely, given that home range is defined as an area in which an animal sleeps and/or breeds and might not be the same as the area over which the animal forages for food. However, if the estimated home ranges were too low, more accurate (higher) values would decrease the risk, assuming that the resulting FI fell below the limiting value of 1.0.

If the home ranges used were too high, more accurate values would increase the estimated risk only for the coyote, mule deer, or hawk (which have home ranges greater than 100 ha [250 ac]). The worst case increase would be about 10-fold for the deer, with a home range of 1,200 ha (3,000 ac). Decreasing this value to 100 ha (250 ac) would increase the deer FI to 1.0 and increase estimated risks by a factor of 12 (1,200/100). This would affect conclusions about risk to deer only marginally. For example, the HI for direct contact with the waste in Cell 1WSS is 0.7, which is close to but not above the 1.0 benchmark of concern. The HI 0.7 multiplied by the estimated rise 12 is 8.4, which is above the benchmark. However, direct contact with the waste was already characterized as very hazardous to deer, and this conclusion would be unchanged. Therefore, although home ranges are not known with high confidence, uncertainty or variation in them would be unlikely to affect the conclusions of the ERA.

The effective energy absorbed from radionuclide decay has a direct proportional effect on the estimated radiation dose. This energy in turn depends on the effective radius assumed for the organism. The smaller the radius, the less energy is absorbed, although this varies across radionuclides due to their different physicochemical characteristics and the relative importance of alpha, beta, and gamma decay. The effective radii assumed for the organisms used in this ERA ranged from 1.4 cm (0.55 in.) (plants) to 30 cm (12 in.) (coyote and deer). An examination of Table D.6.3.7 shows that effective absorbed energies vary by approximately 10-fold across this range, with a number of isotopes showing no difference. Therefore, the effect of the assumed radius on the radiation estimates would be at most 10-fold if the entire dose were due to isotopes with this range of variation in effective absorbed energy. Such differences would not affect the primary conclusions of the ERA.

K.8.3 BIOLOGICAL TRANSFER FACTORS, HALF-LIVES, AND RETENTION FACTORS

The ecological risk estimates for food ingestion in the EIS were directly proportional to the soil-to-plant transfer factors (which determine how much of a contaminant moves into the food chain), the biological half-lives or turnover times of contaminants within organisms, and the fraction of the contaminant retained in the organism at each step of the food chain. Soil-to-plant transfer factors are likely to vary depending on local soil conditions and different plant species. This ERA used published default values that may or may not be applicable to the specific types and locations of plants consumed by the pocket mouse or mule deer. Therefore, these factors therefore probably contribute substantially to the uncertainty in the food ingestion risk estimates. However, as discussed for the source terms, the error or variability would need to be several orders of magnitude before it would affect the conclusions of the ERA. A similar concern exists for biological half-lives and retention factors for chemicals and radionuclides, although again, these would have to be wrong by several orders of magnitude before they by themselves would affect the conclusions of the ERA. The biological half-lives for radionuclides include the radiological half-lives in their calculation. These latter values are known with very high confidence and would not contribute significantly to the uncertainty in the risk estimates.

K.8.4 NO OBSERVED ADVERSE EFFECT LEVELS

The conclusions about potential effects of radiation on ecological receptors relied on single benchmarks of 0.1 rad/day for terrestrial organisms and 1.0 rad/day for aquatic organisms (Volume Three, Appendix D). These benchmarks are independent of specific radionuclides, reflect intense study, and have been widely reviewed. It is therefore unlikely that they contribute importantly to uncertainty in the conclusions of the ERA. However, the estimates of risks due to hazardous chemical exposure are based on the ratio of the estimated intake to the No Observed Adverse Effect Level (NOAEL); see (Volume Three, Appendix D). These values were derived largely from laboratory studies of species other than those of interest in this EIS. There are potential uncertainties in extrapolating from the species used in the laboratory studies to those in the EIS, from the dose ranges used in the studies to those estimated in the field, and from the general conditions in the laboratory to those in the field. All these factors may contribute significantly to the uncertainty in the HI estimates. The HI is inversely proportional to the NOAEL. An examination of Tables D.6.4.4 and D.6.4.5 suggests that errors of 10-to 100-fold in the NOAEL could reduce the high HI values in Table D.6.4.4, for direct contact with the stored waste, to low values below the 1.0 benchmark, if the real NOAELs were higher than those used in the ERA. Similar errors in the opposite direction could increase the low HI values in Table D.6.4.5, for future consumption of groundwater reaching the Columbia River, to values above the 1.0 benchmark. It is therefore possible that uncertainty in the NOAELs for hazardous chemicals could affect the ERA conclusions about chemical hazards associated with direct contact with stored waste or future consumption of groundwater at the maximum concentrations reaching the Columbia River. This would not affect conclusions about the presence or absence of radiological hazards or general conclusions about the need to prevent contact with the tank wastes by ecological receptors.

K.8.5 ECOLOGICAL RISK ASSESSMENT UNCERTAINTY CONCLUSIONS

Overall, the parameters of the equations used to estimate ecological risks would need to vary or be in error by several orders of magnitude to affect the conclusions of the ERA by themselves. Simultaneous variability in multiple parameters in the same direction could do so. For example, increasing IR and FI in Equation 1 above by 10-fold each would increase the estimated contaminant intake by a factor of 100. Such simultaneous variability is possible and would contribute to the overall uncertainty in the risk estimates. Nonetheless, because the ecological risk estimates in this EIS are so different for the various scenarios considered; very high for direct contact with stored wastes and very low for routine releases associated with either the No Action or various remedial alternatives, more detailed analysis would not be considered likely to alter those distinctions. Conversely, more detailed analysis would be unlikely to permit clear distinctions among the remedial alternatives based on potential radiological risks of routine releases, because these latter values are both low and similar to each other. The primary distinction in ecological risks thus remains between the No Action (assuming direct contact with the stored wastes at some future point) and remediation alternatives collectively.

K.9.0 RESULTS

Uncertainty in the conclusions of the TWRS EIS is a consequence of uncertainty in two major areas: the descriptions of the alternatives, with their associated assumptions about tank waste inventories, composition, and remediation technologies; and the consequences analyses, which included assumptions about waste source and release terms, future land uses, environmental transport parameters, and relationships between exposure and risk. The purpose of Appendix K is to discuss the major sources of uncertainty in each of these areas. In addition, a less conservative human health risk analysis is presented to illustrate the implications of making fewer conservative assumptions than were made for the bounding case analyses in the EIS.

Uncertainty in risk analysis is a consequence of two factors: lack of data and natural variability. Lack of data is reflected in our limited knowledge either about the value of constants (e.g., distribution coefficients), or about the statistical parameters (e.g., distribution shape, mean, variance) of things that are inherently variable (e.g., inhalation rates or body weights). Uncertainty due to lack of data can be reduced in principle by more accurate measurements. Uncertainty due to natural variability cannot be reduced by more data, but can be better estimated by acquiring data to characterize statistical distributions of measured variables and by using computer programs to simulate the effect of such variability in the components of equations on calculated values, for example, risk estimates. These combined efforts can reduce systematic uncertainty in the EIS analyses and provide a more thorough understanding of the effects of the remaining uncertainty on the conclusions in the EIS.

K.9.1 UNCERTAINTIES IN THE ALTERNATIVES

There were many uncertainties associated with the alternatives for remediating the tank waste. These uncertainties involved the types of waste contained in the tanks, the effectiveness of the proposed retrieval techniques, waste separations, waste immobilization, and the costs of implementing the alternatives. These uncertainties existed because some of the technologies that may be implemented would be first-of-a-kind technologies, would not have previously been applied to the tank waste, or would not have been applied on a scale as large as would be required for the tank waste, and because only conceptual designs would be available for the alternatives.

K.9.1.1 Major Assumptions

The impact analyses in the EIS required assumptions be made regarding the technologies used for each of the alternatives. These assumptions were based on either the best information available, applications of a similar technology, or engineering judgement. By definition, when an assumption was made, there was some uncertainty associated that was expressed as a reasonable expected range for the assumed value. This section identifies the major assumptions used for the alternatives, describes uncertainties associated with the cost estimates, and presents the results of an uncertainty analysis for the Ex Situ Intermediate Separations alternative.

K.9.1.2 Continued Management and In Situ Alternatives

The following assumptions were made for the Long-Term Management and in situ alternatives. It was assumed that there would be no leaks from the SSTs or DSTs during the administrative control period for the No Action, Long-Term Management, and In Situ Fill and Cap alternatives. The SSTs and DSTs were assumed to maintain their structural integrity throughout the administrative control period for the No Action and Long-Term Management alternatives. The In Situ Vitrification, In Situ Fill and Cap, and the in situ portion of the Ex Situ/In Situ Combination 1 and 2 alternatives were assumed to require additional characterization data to evaluate the acceptability of in-place disposal and to address Resource Conservation and Recovery Act (RCRA) land disposal requirements. The in situ vitrification system was assumed to be capable of vitrifying each tank to the required depth, with no impact of variation in waste composition and inventory on the ability to produce an acceptable waste form. The concentrated liquid waste contained in the DSTs was assumed to be acceptable for gravel filling under the In Situ Fill and Cap alternative.

K.9.1.3 Ex Situ Alternatives

The impact analysis for ex situ alternatives required assumptions about waste retrieval efficiencies, waste loading and blending factors, separations efficiencies, canister sizes and types, and releases to the soil during retrieval. The efficiency of waste retrieval was assumed to be 99 percent. The volume of HLW produced was calculated using the waste inventory, conservative assumptions for waste loading and blending factors, and separations efficiencies. Assumptions about volumes released to the soil during retrieval were made, which directly affected the predictions of the risk consequences resulting from such releases.

K.9.1.4 Schedule

Schedules for construction, operation, and closure were developed for each of the alternatives within the constraints of the Tri-Party Agreement. Schedule constraints would affect the size of the treatment facilities required to process the waste. Following design and construction of a waste treatment facility, the major schedule uncertainty would be the operating duration. Each of the ex situ alternatives was developed using 60 percent overall operating efficiency except for Phase 2 of Phased Implementation, which used 70 percent overall operating efficiency. Operating at higher efficiencies would reduce the operating duration and lower operating efficiencies would increase the duration.

For the alternatives with multiple components, such as retrieval, pretreatment, HLW treatment, and LAW treatment, the overall operating schedule would depend on the efficiency of each component. Uncertainties in the operating schedule would be expected to result in longer operating durations. The operating duration for the ex situ alternatives would be sensitive to the rate at which waste could be retrieved from the SSTs. A low SST sludge retrieval rate could increase the operating duration by 50 percent.

K.9.1.5 Staffing

Staffing estimates were developed for each alternative in support of risk, accident, and socioeconomic impact analysis. These estimates were developed using conservative assumptions for both construction and operating staffing levels. The major uncertainty was associated with the operating schedule. Staffing requirements would be affected by operating efficiencies because efficiency changes would increase or decrease the operating duration and the overall staffing requirements.

K.9.1.6 Resources

The resources required to construct and operate waste treatment facilities were estimated for each alternative using a consistent methodology and common assumptions. The ex situ alternatives and the In Situ Vitrification alternative would have the largest uncertainty for estimated resources. The major uncertainties associated with the estimated resource requirements for the ex situ alternatives included the size and type of facilities required and the volume of LAW and HLW produced.

K.9.1.7 Cost

Cost uncertainties for the various tank waste treatment alternatives were evaluated using a range estimating model. The Ex Situ No Separations (Vitrification) alternative had the largest estimated cost range due to the disposal cost for the large number of HLW packages that would be produced. The In Situ Vitrification alternative had the highest cost range on a percentage basis due to the uncertainties associated with implementing this technology for remediation of the tank waste.

K.9.2 UNCERTAINTIES IN SOURCE AND RELEASE TERMS

Source terms refer to the inventory, which is the total quantity of the hazardous material within the tanks, and to the release term, which is the amount released to environmental media such as air, groundwater, surface water, and soil under normal or accident conditions. Uncertainties associated with source terms included the characteristics and composition of the waste in the tanks and the specific performance capabilities of waste retrieval and processing technologies. Information needed to more thoroughly determine the composition and characteristics of the tank waste currently is being obtained through waste characterization studies. DOE has identified 46 key radionuclides for tracking in development of a "best basis inventory" for Hanford Site tank wastes. These include the radionuclides that dominate the risk estimates in this EIS: C-14, I-129, Np-237, Pa-231, Se-79, Tc-99, and U isotopes. This information will be incorporated into any NEPA analysis of tank farm closure alternatives.

K.9.3 UNCERTAINTIES IN TRANSPORT

Uncertainties in the human health and ecological exposure assessments depend in part on the uncertainties of estimated transport of contaminants from sources through air, soil, groundwater, and surface water to potential receptors. The principal sources of uncertainty of soil and groundwater transport include the physical and chemical mechanisms of contaminant transport through the vadose zone to the groundwater, the rates of infiltration into natural soil and through a protective barrier cap, distribution coefficients (K_d) of contaminants, assumptions about future groundwater flow direction due to assumed decay of groundwater mounds onsite and to climate change, assumptions about future vadose zone thickness due to climate change, assumptions about vadose zone transport in one-dimensional flow and transport simulations, and estimates of releases during retrieval.

The primary sources of uncertainty in estimating surface water transport were associated with the rate of dilution of contaminants in groundwater entering the Columbia River. These sources were the groundwater flow rate and river flow rate, including seasonal and diurnal fluctuations ranging from 2,300 m^3/s (81,000 ft^3/s) to 7,100 m^3/s (250,000 ft^3/s); plus turbulence of river flow, which depends on velocity; irregularities in the stream channel, including bends; and width of the river. All of these factors ultimately would depend on the total flow in the river at the point(s) where contaminated groundwater is discharged.

Estimation of transport through air depends on air dispersion modeling. Various assumptions and other factors can introduce uncertainty to these estimates. These uncertainties can be broadly separated into uncertainty inherent in the models, uncertainty in the data used as model inputs, and uncertainty in interpretation of model outputs. Input assumptions included pollutant release characteristics (form, particle size distribution, emission rate, temperature, flow rate), meteorological conditions (ambient temperature, mixing height, stability, wind speed and direction, atmospheric temperature, wind speed profile), and pollutant transport behavior (dispersion, plume rise, interaction with terrain). Model output interpretation required converting 1-hour average values to 3-, 8-, and 24-hour average values using conversion factors. These factors involved an implied assumption regarding the persistence of the meteorological condition producing the highest 1-hour impact. For example, conservative meteorological conditions that produced the highest 1-hour concentration could be expected to persist for most of a 3-hour period, and to a lesser degree, over an 8- or 24-hour period. The midpoint conversion factor values of 0.9. 0.7, and 0.4, respectively, were considered appropriate for this study.

K.9.4 UNCERTAINTIES IN HUMAN EXPOSURE ASSESSMENT

Uncertainties in the human health exposure assessment were divided into two parts. The first part was associated with the exposure parameters used in the post remediation land use scenarios. The second part was associated with the accidental release scenarios. In both cases, Monte Carlo simulations were used to evaluate the uncertainty in the exposure assessment and to establish the parameters that contributed the most to the uncertainty in the exposure assessment (i.e., sensitivity analysis).

In the Monte Carlo approach, PDFs were used to represent the range of values of a given parameter. The effects of simultaneous variations over these ranges on the exposure assessment then were examined using a computer software package (Crystal Ball). These computations were repeated a large number of times to produce complete PDF of the output functions. Statistical summaries of the results then were plotted to help interpret the data.

K.9.4.1 Post-Remediation Land-Use Scenarios

The percentiles of the Monte Carlo-based PDFs were computed and compared to the fixed point estimates of the same function. Two important conclusions can be drawn from these results. First, as expected, the fixed point estimates in the exposure assessment generally lie at the high end of the PDF or approximately the 95th percentile. This is expected, because the fixed point estimate is intended to be an upper bound estimate. Second, the mean of the Monte Carlo-based PDF generally was approximately one order of magnitude lower than the fixed point estimate. This result suggests that the exposure estimates in the EIS were higher-than-expected values or best estimates by approximately an order of magnitude.

K.9.4.2 Accidental Release Scenarios

A Monte Carlo uncertainty and sensitivity analysis also was conducted on the parameters used to compute LCFs or the probability of contracting cancer from accidental releases associated with the remedial actions. The sensitivity analysis indicated that the parameters that contributed the most to the uncertainty in the LCF for the accidental release scenarios, as measured by rank correlation, were the ULD, atmospheric dispersion coefficient (Chi/Q), release volume, IR, and LCF conversion factor.

Comparing the mean and percentile estimates of the LCF distributions for the four accidental release scenarios with the fixed point estimates derived using the upper-bound values indicated that the LCFs based on the upper-bound values were in all cases greater than the 100th percentile of the LCF PDF. The means of the LCF PDFs were approximately one order of magnitude lower than the upper-bound fixed point estimates. These results suggest that the LCF estimates in the EIS are upper bound values. The true probability of contracting cancer or fatalities resulting from cancer actually could be much less than the predicted value.

K.9.5 UNCERTAINTIES IN HUMAN HEALTH RISK

The uncertainties associated with the TWRS EIS risk estimates included parameters used in the equations relating exposure to risk and the historical data on worker risks and accidents used in the evaluations of potential accident impacts. To estimate risk, information must be available on dose-response relationships, which would define the biological response from exposure to a contaminant. Although human epidemiological data were used for developing radiological and nonradiological chemical dose-response models, this information also was developed in laboratory tests using animals exposed to relatively high doses. Therefore, uncertainty is inherent in dose-response relationships, including extrapolating from effects in animals at high doses to potential effects in humans who most often are exposed at much lower doses.

Uncertainty associated with the derivation of toxicity values also affects the level of confidence in human health risk estimates. Sources of uncertainty associated with published toxicity values include the following:

- Use of dose-response information from effects observed at high doses to predict effects at low levels expected in the environment;
- Use of data from short-term exposure studies to extrapolate to long-term exposure or vice versa;
- Use of data from animal studies to predict human effects; and
- Use of data from homogeneous animal populations or healthy human populations to predict effects on the general population.

The summation of cancer risk across pathways or for multiple pathways makes the total cancer risk more conservative. This is because each slope factor for each chemical carcinogen is an upper 95th percentile estimate, and such probability distributions are not strictly additive. The risk values calculated for the post-remediation scenario in the TWRS EIS were a conservative bounding estimate. The uncertainty in the risk values for certain receptors increases as the time to the future increases. Less uncertainty was associated with the risk values at 300 years than the risk estimates at 500, 2,500, 5,000, and 10,000 years.

By far the greatest uncertainty in the routine remediation risk was associated with the source data, which were based on the estimated inventory and source terms (i.e., the amount of chemicals and radionuclides released to the environment). Other contributors to the routine risk uncertainty were airborne transport of the released chemicals and radionuclides; accumulation of contaminants in food products; production and distribution of food products; lifestyle and diet of specific individuals; food consumption rates; and dose conversion factors.

The risk estimates for the post-remediation and intruder scenarios were associated with more uncertainty than facility routine operation risk because they involved uncertainties associated with the future land use and intrusion into residual waste, in addition to modeling. Finally, the MEI risk estimates generally involved a greater level of uncertainty than population risk estimates. The greatest uncertainty in calculating the post-remediation intruder risk was associated with the source data. Source terms were based on the estimated inventory and an average tank within the eight aggregated tank farms of the 200 Areas (Volume Two, Appendix A). Additional information regarding the source term would decrease the uncertainty in the risk estimate. The relative uncertainties associated with the dose conversion factors were not as important as the source data, source terms, and exposure pathway parameters.

K.9.5.1 Uncertainties in Ecological Risk

The ERA for this EIS used a screening level methodology to estimate potential radiological and chemical hazards to a suite of representative terrestrial receptors: the Great Basin pocket mouse, coyote, mule deer, red-tailed hawk, and loggerhead shrike. Pathways considered for the No Action alternative were food and water ingestion (all receptors except the mouse, which was assumed to obtain all water from metabolic sources), incidental soil ingestion (mouse and mule deer, coincident with consumption of vegetation), inhalation of routine releases (all), and direct external exposure (mouse, while in a burrow). Potential hazards to aquatic organisms were evaluated using the CRITRII program developed at the Pacific Northwest National Laboratory.

Overall, the parameters of the equations used to estimate ecological risks would need to vary or be in error by several orders of magnitude to affect the conclusions of the ERA by themselves. Simultaneous variability in multiple parameters in the same direction could do so. For example, increasing both water ingestion rates and the fraction of water obtained from a contaminated source by 10-fold would increase receptors estimated contaminant intake by a factor of 100. Such simultaneous variability is possible and would contribute to the overall uncertainty in the risk estimates. Nonetheless, because the ecological risk estimates in this EIS were so different for the various scenarios considered (very high for direct contact with stored wastes and very low for routine releases associated with either the No Action or various remedial alternatives) more detailed analysis was not considered likely to alter those distinctions. Conversely, more detailed analysis was unlikely to permit clear distinctions among the remedial alternatives based on potential radiological risks of routine releases, because these latter values were both low and similar to each other. The primary distinction in ecological risks thus remains between the No Action (assuming direct contact with the stored wastes at some future point) and remediation alternatives collectively.

K.9.6 CONCLUSIONS

The scope of the tank waste disposal action and alternatives analyzed in the TWRS EIS was such that a number of components of actions and analyses contributed varying degrees of uncertainty to the assessment of impacts as discussed above. Some of the components were well characterized and the uncertainties were well known and documented. Other components were better characterized as estimates and the uncertainties were not known or were also estimated. However, the major sources of uncertainty were associated with a few major components of the proposed action and alternatives. Following is a brief discussion of those major components of uncertainty and DOE or other actions which would be expected, in time, to reduce the level or range of uncertainty for that component.

K.9.6.1 Engineering

Uncertainties related to engineering included facility, process, and equipment design, and performance. The flowsheets and facility designs for the TWRS alternatives were preconceptual, based on design information and performance criteria that are in the early planning stages and involve considerable engineering judgement. Engineering design uncertainties will be reduced or better defined as investigations are completed, disposal decisions are made, and engineering design proceeds to preliminary and ultimately definitive design. These efforts would include pilot-scale testing and process demonstration on the tank waste before full scale implementation.

K.9.6.2 Waste Inventory

Uncertainties regarding waste inventory relate to the waste type, form, and quantity of tank waste constituents. These uncertainties contributed in turn to the uncertainty of source terms, release rates and transport estimates (Figure K.1.0.1). The waste inventory data used in developing the alternatives and their associated impacts were derived from model predictions and sample analyses performed to date. DOE has an ongoing waste characterization program in place to better define the quantity, content, form, and characteristics of the tank waste that will ultimately reduce the inventory-related uncertainties. DOE has identified key radionuclides for tracking in developing a "best basis inventory" for Hanford Site tank waste. These include the radionuclides that dominate the risk estimates in this EIS: C-14, I-129, Np-237, Pa-231, Se-79, Tc-99, and U isotopes. This information will be incorporated into any NEPA analysis of tank closure alternatives. As part of this program, DOE is currently developing the HTI program that will provide information on the characteristics of the tank residuals and the capability of retrieval systems to deal with difficult-to-remove SST wastes. This program, which will reduce the uncertainties associated with residual waste, includes demonstrations of capabilities to quantify residual waste volume and technologies for sampling and characterizing the residual waste.

K.9.6.3 Waste Transport

Uncertainties regarding waste transport include source terms (type, quantity, form, composition, concentration, solubility), and release rates for tank residuals and LAW, vadose zone characteristics, groundwater flow characteristics, transport mechanisms, and rates. Recent observations of relatively immobile contaminants at depths of up to 38 m (125 ft) below the tanks are not fully explained with interstitial flow and may indicate there are other transport mechanisms in effect. These observations are currently the focus of a DOE program. The initial phase of the program is to determine if the observations are representative of extensive vadose zone contamination beneath the tanks or if they are related to other phenomena such as borehole cross contamination. DOE is also currently developing criteria and technologies to identify leaks and limit releases during retrieval.

K.9.6.4 Exposure Scenarios

The TWRS EIS has assessed an extensive and well defined suite of potential human exposure scenarios including an array of potential remediation and post remediation receptors. The scenarios included a variety of Hanford land uses (farming, industry, recreation, Native American subsistence), a variety of receptors (resident, worker, farmer, recreational user, intruder) and a variety of pathways. Uncertainties related to exposure scenarios include the degree to which Hanford land or groundwater would be accessible or restricted, the location, timing, and duration of exposures to contaminants, and the density of user populations. DOE has an ongoing program to determine future land uses for the Hanford Site including preparation of a Comprehensive Land Use Plan. These efforts, in combination with those described in Sections K.9.1 through K.9.3, will both reduce the total uncertainty in the TWRS risk analyses and better characterize that which remains.

ATTACHMENT 1

Explanation of Input Distributions Used in the Monte Carlo Methodology

This attachment explains the information sources and rationale used in deriving the input distributions used in the Monte Carlo uncertainty and sensitivity exposure analysis. This attachment is ordered by exposure scenario (e.g., industrial, residential) with input distribution explanations given for the exposure route which resulted in the greatest risk for each particular exposure scenario.

Industrial Exposure Scenario

The industrial exposure scenario is based on worker exposure over a 20-year duration. The scenario involves mainly indoor activities, although outdoor activities (e.g., soil contact) are also included. The air inhalation rate is 20 m^3 per day for a worker and external exposure occurs 8 hours per day. Inhalation of contaminants occurs 250 days per year and external exposure occurs for 146 days per year.

EF (exposure frequency)

Units: days per year
Distribution used: triangular (likeliest 245, maximum 307, minimum 156)
Source: EPA 1989

This input represents the number of days per year that a typical worker would spend in the workplace. The likeliest value for EF was established using the rationale that the worker works two weekends per year and takes two weeks' vacation and two weeks' sick leave. The minimum value for EF was established by assuming that the worker is part-time and only at the site approximately 60 percent of the time. The maximum value for EF was based on a person taking two weeks' vacation, two weeks' sick leave, and working all but 15 weekends per year.

ED (exposure duration)

Units: years
Distribution: lognormal (mean 7.3, standard deviation 8.7)
Source: Department of Labor 1992

This input represents the number of years that the individual being modeled will spend at a particular job location within the contaminated area. After considering the information in the EPAs Exposure Factors Handbook (EPA 1989) and after considering various factors that could impact ED, it was determined that the input would be characterized using the data from a study conducted by the Department of Labor completed in 1992. The distribution used for ED is a lognormal distribution based on a mean standard deviation presented by the Department of Labor report. The maximum value is 30 years, which is the upper bound time specified by the report for a worker at any one given job, and which is also the value specified by the EPA.

IR (inhalation rate)

Units: cubic meters per day
Distribution: triangular (likeliest 18.9, maximum 32.0, minimum 6.0)
Source: EPA 1985

This input represents the amount of air that is breathed in during a typical day at work by an adult under an industrial exposure scenario. Layton (Layton 1993) has shown that inhalation rates vary with body weight and the type of activity (i.e., light, medium, or heavy). For this evaluation, a triangular distribution was used based on adults working at light activity levels.

Residential Exposure Scenario

The residential scenario is based on exposures over 30 years duration to an individual residing onsite. The individual is assumed to be exposed to contaminated soil, air, surface water, and groundwater, and homegrown fruits and vegetables 365 days per year. The exposed individual was assumed to ingest 2 L (0.5 gal) of contaminated water per day, 365 days per year for 30 years.

EF (exposure frequency)

Units: days per year
Distribution used: triangular (likeliest 345, maximum 365, minimum 180)

Source: Smith 1994

This input represents the number of days per year that the typical behavior being used to characterize risk to the target population takes place. Providing an example of a nontypical day that would be excluded from consideration when generating an EF input may be helpful in understanding the purpose of the input. Days taken during the year as vacation, where the person is away from work, would not be considered typical since exposure parameters are likely to differ from those associated with a typical day in that persons life.

The likeliest value for EF was established using the rationale that two weeks spent away from home was a plausible likeliest value for EF. The minimum value for EF assumes that a person spends 50 percent of his or her time at home and the rest away from home. The maximum value for EF assumes that the person spends all of his or her time at home.

ED (exposure duration)

Units: years
Distribution: lognormal (mean 11.4, standard deviation 13.7)
Source: Department of Labor 1992

This input represents the number of years that the individual being modeled will reside at a residence located within the contaminated area. After considering the information in the EPAs Exposure Factors Handbook (EPA 1989) and after considering various factors that could impact ED, it was determined that the input would be characterized using the data from a study conducted by the Department of Labor completed in 1992. The distribution used for ED is a lognormal distribution based on the mean and standard deviation presented by this report. The maximum value is the upper bound time specified by the report for a worker at any one given job.

IR (drinking water ingestion rate)

Units: liters per day
Distribution: lognormal (mean 1.12, standard deviation 1.63)
Source: Rosenberry-Burmaster 1992

Direct ingestion of radionuclides in tap water is an important exposure pathway that often dictates groundwater remediation at contaminated sites. The IR input represents the amount of drinking water ingested during a typical day by an adult under a residential exposure scenario.

Native American Scenario

The Native American scenarios are intended to include a wide range of activities from reserved rights related to traditional lifestyles and preservation of natural and cultural resources to those specifically delineated in the Treaties. Specific activities include hunting, gathering, collecting, fishing and processing of the catch along the shoreline, and pasturing of livestock, as well as ceremonial, educational, seasonal, social, and trade activities.

EF (exposure frequency)

Units: days per year
Distribution used: triangular (likeliest 345, maximum 365, minimum 180)
Source: Smith 1994

This input is the number of days per year that the typical behavior being used to characterize risk to the target population takes place. An example of a nontypical day that would be excluded from consideration when generating an EF input may be helpful in understanding the purpose of the EF input. Days taken during the year as vacation, where the person is away from work, would not be considered typical since exposure parameters are likely to differ from those associated with a typical day in that persons life.

The likeliest value for EF was established using the rationale that two weeks spent away from home seemed a plausible likeliest value for EF. The minimum value was based on a scenario in which a person spends 50 percent of his or her time at home and the rest away from home. The maximum value was based on a person spending 100 percent of their time at home.

ED (exposure duration)

Units: years
Distribution: lognormal (mean 11.4, standard deviation 13.7)
Source: Israeli-Nelson 1992

This input is the number of years that the individual being modeled will reside at a residence located within the contaminated area. After considering the information in the EPAs Exposure Factors Handbook (EPA 1989) and various factors that could impact ED, it was determined that the input would be characterized using the data from a study conducted by the Department of Labor in 1992. The lognormal distribution used for ED is based on that report. The maximum value is 70 years, which is the upper bound time specified in the Native American scenario.

IR (fish ingestion rate)

Units: grams per day
Distribution used: triangular (likeliest 140, maximum 1,080, minimum 30.0)
Source: DOE 1996 and EPA 1989

Consumption rates for recreationally caught fish from large bodies of water have a 50th percentile average of 30 g/day and a 90th percentile average of 140 g/day (EPA 1989). Therefore, for purposes of this scenario, the fish ingestion PDF was approximated by a triangular distribution.

VF (volatilization factor)

Units: liters per cubic meter
Distribution: triangular (likeliest 0.1, maximum 0.3, minimum 0)
Source: Andelman 1990

For groundwater, an upper bound volatilization factor (VF) based on uses of household water (e.g., showering, laundering, dish washing) was used. A VF of 0.1 L/m^3 was used for household activities. The transfer of contaminants from water to a Native American in a sweat lodge was also estimated using a VF similar to that proposed by EPA (Andelman 1990). The steam in the sweat lodge is generated by pouring water onto heated rocks. A VF of 0.3 L/m^3 is used for all nonvolatile contaminants, a factor of 2.5 is used for all VOCs, and a factor of 0.5 is used for radon. Therefore, for the Native American scenario, the VF probability density function was modeled as a triangular PDF with a most likely value of 0.1 L/m^3, maximum value of 0.3 L/m^3, and minimum value of zero.

Total Health Impacts for Hanford Site Users

The total adverse health impacts to a hypothetical future resident of the Hanford Site is expressed as the total cancer fatalities over a 10,000-year period. The cancer fatalities are calculated by first computing the total cancer risk for a given population and then dividing by the dose to risk conversion factor for cancer incidence and cancer fatalities (ICRP 1991). The parameters driving the uncertainty are the population density and the length of time for a life span or generation.

P (population density)

Units: persons per square kilometer
Distribution used: triangular (likeliest 3, maximum 5, minimum 1)
Source: professional judgment and WSDFM (1994)

The population density describes the number of people in a given area that will live at some hypothetical time in the future at the Hanford site. The current estimates of the farming population density surrounding the site give a value of approximate 5 persons/km^2. The triangular distribution for population density was chosen in order to estimate the uncertainty in the cancer fatalities at a population density of as low as 1 person/km^2.

D (Duration of each generation)

Units: years
Distribution: normal distribution (mean 75 years, standard deviation 7.5 years)
Source: EPA 1989

This input is used to represent the life expectancy for the each generation. Although 70 years has been widely used in the past, current data suggest that 75 years would now be a more appropriate average value.

Intruder Scenario

The post drilling scenario has three exposure pathways: exposure to airborne contamination via inhalation, external exposure to penetrating radiation, and consumption of contaminated produce. For the post drilling scenario, 0.35 m^3 of waste are distributed throughout a 15-cm-deep plow layer in a garden that is 2,500 m^2 in area. The individual is assumed to spend 4,380 hr/year residing at home (indoors), 1,700 hr/year outdoors, and 100 hr/year outdoors in gardening activities on the Site. The sensitivity analysis for the intruder scenario indicated that the intruder effective dose is most dependent in order of rank upon soil concentration, external exposure time, depth to the contamination, and the soil density.

Soil Concentration

Units: picocuries per gram
Distribution used: triangular (likeliest 9.9 E+05 maximum 1.7 E+06 minimum 4.4 E+05)
Source: professional judgment and Rittman 1994

The concentration of the contaminant in soil is a function of the diameter of the well, the thickness of the waste layer, the garden surface area, and the soil density. The thickness of the waste layer is assumed to be a constant 5 m (16 ft), although some uncertainty is associated with this parameter. The uncertainty associated with the surface area of the garden and the soil density are treated separately below. The diameter of the well excavated at the site was assumed to vary as a triangular distribution. The maximum value was assumed to be the point estimate of 30 cm (12 in.) and the most probable and minimum values were selected to be 22.5 cm (9 in.) and 15 cm (6 in.), respectively. The rationale for this assumption is that the well diameter could conceivably be three-fourths or one-half the point estimate. The corresponding triangular distribution for the soil contaminants concentration had the values stated above.

External Exposure Time

Units: hours
Distribution used: triangular (likeliest 1,800, maximum 3,260, minimum 676)
Source: professional judgment and EPA 1989

For estimating external exposure from the soil contamination, the house was assumed to reduced the dose rate to one-third the direct dose rate. Therefore, the average time exposed at the unshielded dose rate is:

$$(1{,}800 \text{ hr/year})*1 + (4{,}380 \text{ hr/year})*(1/3) = 3{,}260 \text{ hr/year}$$

For the purposes of the Monte Carlo assessment, the minimum external exposure time was based on EPAs analysis of activity patterns in United States households (EPA 1989). The most likely value was chosen to represent 100 percent shielding of the receptor by the house.

Depth to Contamination

Units: centimeters
Distribution used: triangular (likeliest 15.0, maximum 22.5, minimum 7.5)
Source: EPA 1989 and Rittman 1994

The likeliest depth to the contaminants was chosen to be 15 cm or the tilling depth (Rittman 1994). However, due to leaching and other factors, surface soil was considered to extend to 22.5 cm or to be as shallow as 7.5 cm.

Soil Density

Units: grams per cubic centimeter
Distribution used: uniform (maximum 1.50, minimum 0.50)
Source: Rittman 1994 and DOE 1996

Published soil densities for the Hanford Site range from 0.5 g/cm^3 (DOE 1996) to 1.5 g/cm^3 (Rittman 1994). Therefore, the soil density distribution was assumed to be uniform with likeliest value 1.0.

Total Health Impacts Along the Columbia River

This scenario is used to estimate the dose to a population exposed to contamination from the Columbia River. The contamination enters the Columbia River as a result of groundwater flow into the river. Different contaminants will enter the groundwater and reach the Columbia River at varying times in the future.

Total cancer fatalities are calculated using factors that relate the number of fatal cancers to the curies of each contaminant released to the river. These factors were calculated using a computer program which estimates the time integral of collective dose over a period of up to 10,000 years for time variant radionuclide release to surface waters, such as rivers (DOE 1987).

The dose estimates for the Columbia River scenario indicate that of the three principal routes of exposure (i.e., external, ingestion, and inhalation), ingestion is the principal route, followed by inhalation and external exposure. A Monte Carlo sensitivity analysis indicated that the parameters which most affect the equivalent dose are in rank order: soil to plant transfer factor, root ingestion rate, Columbia River flow rate, total population exposed, months per year of irrigation, and soil area density.

Root Ingestion Rate

Units: kilogram per year
Distribution used: triangular (likeliest 55.7, maximum 73.0, minimum 0.0)
Source: DOE 1996 and Rittman 1994

The root ingestion rate is the quantity of rooted vegetables consumed on a yearly basis by a resident along the Columbia River. For nonleafy vegetables, this value is approximately 55.7 kg/year (Rittman 1994). A more recent publication which deals directly with potential impacts to the Columbia River by contaminants from the Hanford Site states a value of 200 g/day or approximately 73 kg/year (DOE 1996).

Columbia River Flow Rate

Units: cubic feet per second
Distribution used: triangular (likeliest 8.1E+04, maximum 2.5E+05 minimum 3.6E+04)
Source: Volume One

The flow rate of the Columbia River is important in that it is used to estimate the amount of dilution that a contaminant would undergo once groundwater discharges to the river. Flows through the Reach fluctuate significantly and are controlled by operations at Priest Rapids Dam. Daily average flows range from 3.6E+04 ft^3/sec to 2.5E+05 ft^3/sec.

Months Per Year of Irrigation

Units: months per year
Distribution used: triangular (likeliest 6.0, maximum 7.0, minimum 5.0)
Source: Rittman 1994 and professional judgment

This parameter is the number of months per year that plants are irrigated with contaminated Columbia River water. A default value of six months per year has been assumed for the Hanford Site (Rittman 1994). However, in order to place some uncertainty on this value, irrigation has been assumed to occur for six months plus or minus 1 month to account for dry and wet years.

Soil Area Density

Soil area density is the product of soil density and the depth to the contamination. The same distributions used in the Monte Carlo approach for the intruder scenario for these distributions were used in the present scenario.

Soil to Plant Transfer Factor (root)

Units: curie per kilogram dry weight of vegetable to curie per kilogram of soil
Distribution: lognormal (mean 0.50, standard deviation 0.25)
Source: professional judgment

The soil to plant transfer factor accounts for the amount of contaminant that will be taken up from the soil through the roots of a plant. The most recent published value for this factor is 1.0 (Rittman 1994) for Np which is two orders of magnitude larger than the last published value (PNL 1986). However, examination of the most recent published values for this factor for other radionuclides (Rittman 1994) indicates that in general, the soil to plant transfer factor is between 0.01 and 1.0. Therefore, the distribution used for the Monte Carlo analysis was a lognormal with a mean value of 0.50 and standard deviation of 0.25. Examination of this probability distribution reveals that the selected distribution captures the range of values between 0.01 and 1.0.

APPENDIX L

DRAFT EIS COMMENTS AND AGENCY RESPONSES

INTRODUCTION

The U.S. Department Of Energy and the Washington State Department of Ecology added Appendix L, Response to Public Comments, to the Tank Waste Remediation System (TWRS) Environmental Impact Statement (EIS) to fully address and respond to public comments on the Draft EIS. In addition, DOE considered public comments, along with other factors such as programmatic need, short- and long-term impacts, technical feasibility, and cost, in arriving at DOE's preferred alternative. During the public comment period for the Draft EIS, more than 350 individuals, agencies, Tribal Nations, and organizations provided comments. This volume represents a broad spectrum of private citizens; businesses; local, State, and Federal officials; Tribal Nations; and public interest groups.

Appendix L contains the comments on the EIS received during the public comment period and DOE and Ecology responses to those comments. Frequently, identical or similar comments were provided by more than one individual, and in such cases, DOE and Ecology grouped the comments and prepared an in-depth response for each group. These responses are included as the response to the first comment. Subsequent similar comments refer the reader to the initial response. In compliance with the provisions of the National Environmental Policy Act (NEPA), Council on Environmental Quality (CEQ) regulations [40 CFR 1502.14(e)], and Washington State Environmental Policy Act (SEPA) Rules (WAC 197-11) public comments on the Draft EIS were assessed and considered both individually and collectively by DOE and Ecology. Some comments resulted in modifications to the EIS. Other responses contained an explanation of the reasons that the comments did not warrant any further response or modification to the EIS. The final decision on which alternative to implement will be made following publication of the Final EIS and will be documented in a Record of Decision (ROD). The public comments on the Draft EIS will be considered when making the final decision. The ROD will be published no sooner than 30 days after the publication of a Notice of Availability for the Final EIS in the Federal Register.

HOW DOE AND ECOLOGY CONSIDERED PUBLIC COMMENTS IN THE NEPA PROCESS

As required in the CEQ regulations, the Final EIS identifies DOE's and Ecology's preferred alternatives. The preferred alternatives were identified based on consideration of environmental impacts, regulatory compliance, DOE and Waste Management programmatic missions, public comments, and DOE policy. Public input considered in DOE's and Ecology's identification of preferred alternatives included concerns, preferences, and opinions regarding the activities addressed in the EIS, as well as expectations of DOE in making the decisions on environmental restoration and waste management programs at the Hanford Site.

CHANGES TO THE EIS RESULTING FROM PUBLIC COMMENTS

A major purpose of NEPA and SEPA is to promote efforts that will prevent or reduce damage to the environment by ensuring informed decision making on major Federal actions that significantly affect the quality of the human environment. Consideration of public comments on the Draft EIS helps ensure that the EIS is an adequate decision making tool; accordingly, this EIS has been enhanced, as appropriate, in response to public comments. Based on review of public comments, along with with consultations held with commenting agencies, State and Tribal governments, primary EIS enhancements include the following.

- Discussion and analysis associated with the disposal of high-level waste at the potential national geologic repository were reviewed, clarified by separating the discussion and analysis from other components of the alternatives, and current data and formulas for calculating costs were added to Volumes One and Two, as appropriate.

- The option of longer interim onsite storage of high-level immobilized waste pending availability of an offsite geologic repository was included in the Final EIS.
- In Volume One, Section 5.11 and Volume Three, DOE revised the risk analysis to include a Native American subsistence user scenario. This analysis compared impacts of each alternative to a future population of individuals who would reside on the Hanford Site and subsist in a traditional lifestyle. This scenario was developed in consultation with affected Tribal Nations.
- Additional consultation with the affected Tribal Nations is reflected in the environmental justice analysis and throughout the EIS, as appropriate.

As committed to in the Draft EIS, a discussion of emerging data regarding vadose zone contamination beneath the tanks resulting from past leaks has been added to the Final EIS in Volume One, Sections 4.2 and 5.2, Appendix F, and Appendix K. The data were unavailable for inclusion in the EIS at the time the Draft EIS was published. Much of the data presented in the Final EIS are based on preliminary analysis of the vadose zone contamination, and thus the EIS presents several scenarios that are currently under review by DOE regarding the cause, nature, and extent of the contamination.

The Draft EIS contained an analysis of uncertainties for each relevant component of the environment (e.g., risk, waste inventory, groundwater migration) in the applicable section of the EIS. For the Final EIS, the evaluation and discussion of uncertainties was expanded and presented together in Volume Six, Appendix K.

Other enhancements to the EIS included modifying Phase 2 of the Phased Implementation alternative to include construction and operation of two waste treatment facilities. Accident discussions and analysis were reviewed, and emerging data were added to Volume One, Section 5.12 and Appendix E. The EIS was also revised to reflect 1995 Site environmental monitoring and reporting. Finally, DOE expanded the EIS analysis of a variation to the Ex Situ/In Situ Combination alternative (known as Ex Situ/In Situ Combination 1 alternative in the Final EIS) presented in the Draft EIS. This alternative was described in the Draft EIS in the cover letter and preface to Volume One and is called the Ex Situ/In Situ Combination 2 alternative in the Final EIS. The discussion and analysis for this alternative are presented in Volume One and Appendix B. DOE added an expanded discussion and analysis of uncertainties to the Final EIS.

Editorial changes were made to the EIS to correct errors, none of which were considered substantive, and to clarify discussions.

HOW TO USE APPENDIX L TO LOCATE RESPONSES

Three indices, Tables L.1, L.2, and L.3, are provided as cross references for specific comments and corresponding section number in Appendix L. Table L.1 is organized by individual or organization providing comment, listed alphabetically; date the comment was provided, if the same individual or organization submitted multiple comments; comment document number assigned and method used to submit the comment, whether written or verbal; comment number, and corresponding Appendix L section number. Individuals providing comments by postcard will find the associated response section by locating "Postcard Correspondence" in column 1 (Individual/Organization [Date Submitted]). Individuals who provided comments by means of the public interest group survey may find the compiled results of the survey, along with references to other Appendix L sections, in Section L.3.9. Table L.2 is organized by section number in Appendix L, page number, and associated comment numbers. Table L.3 lists comment numbers along with their section number and page number.

To find a response to a specific or group of comments, please use the following procedure.

1. Turn to Table L.1 and locate the individual or organization listed in Column 1, and note the response section number(s) assigned to that comment document in Column 4.
2. Following the section number, the page number is listed in Column 5 for the page on which comment and response are listed in numerical order.
3. Turn to the appropriate page(s) to find a response to the comment.

Use the same process to find comments provided by other individuals and organizations. Throughout the appendix, when responses to a particular comment are related to responses to other similar comments, the comment number of the similar comment or comments is provided. To locate the similar comments and associated responses, refer to Table L.3, which lists the comments numerically and the corresponding page number. In an effort to be as complete as possible and address all issues and concerns, each written comment or transcript of an oral comment was reviewed for specific concerns or recommendations. Each concern or recommendation was given a specific comment number and assigned to a specific number in Volume Six, Appendix L most closely corresponding to the nature of the comment. If your comment document contains more than one comment, repeat steps 2 and 3 for each comment because each response could fall under a different response section.

HOW TO FIND REFERENCE DOCUMENTS

Technical references and other supporting documentation cited in Appendix L are available in the DOE Reading Rooms and Information Repositories listed at the end of the Summary and in Volume One, Section 8.0.

DRAFT EIS COMMENTS AND AGENCY RESPONSES

ACRONYMS AND ABBREVIATIONS

Section L.1.0 is unavilable electronically.

L.2.0 PURPOSE AND NEED FOR ACTION

Comment Number 0005.36

Swanson, John L.

Comment The term "low-activity waste" is used incorrectly on page 2-1: at least the usage there does not agree with the distinction drawn on pages 1-3 and 6-18 that LAW is tank waste remaining after the removal of the practicable amount of HLW. By this distinction, how can there be any LAW in the tanks now? As I understand it, all of the tank wastes except for the NCRW and PFP tanks are HLW by definition; they will be pretreated to divide them into HLW and LAW fractions, but LAW does not exist until after pretreatment has happened. If this understanding is not correct, you had better revise your definition of LAW so that it is consistent with whatever it is that you mean. (I would be happy to try to assist in such a revision if it were explained to me what is really meant).

Response The use of the term LAW on page 2-1 is consistent with the definition of LAW provided in Volume One, Section 1.0. LAW is the waste remaining after the removal of as much of the radioactivity as is practicable from HLW. As indicated in Volume One, Section 1.1, during the 1950's and 1960's uranium, cesium, and strontium were separated from the waste in some of the SSTs. Based on this earlier waste separations, some of the SSTs may be able to be classified as containing LAW. However, due to incomplete tank-by-tank waste characterization, it is not possible at this time to conclude how many or which tanks could potentially be considered for classification as LAW tanks.

As discussed in Volume One, Section 6.2, the correct classification of the waste from each tank will be required to determine which regulations are applicable to the disposition of the waste in each tank. Thus, it is possible that when tank waste characterization is complete, some of the tanks may be classified as LAW tanks. The waste from these tanks then could be processed accordingly. For example, under the preferred alternative, Phased Implementation, the waste from tanks determined to contain only LAW could be directly treated at the low-activity vitrification facility without requiring pretreatment. Please refer to the responses to Comment numbers 0005.25, 0041.01, and 0072.41.

Comment Number 0019.02

WDFW

Comment WDFW has reviewed, the purpose and need for action, and requests additional language be incorporated for clarification. Specifically, the need for action should state 67 SSTs are known or are assumed to have leaked 2.3 million to 3.4 million liters of hazardous waste to the groundwater, thus the need to remediate the source (tank waste) to prevent further contamination of groundwater. As long as an uncontained liquid waste source exists, it will continue to contribute to groundwater contamination and ultimately end up in the Columbia River.

Response The transfer of the liquid waste from the SSTs, many of which have leaked or could leak in the future, into the DSTs greatly reduces the potential for additional leaks into the soil column. A separate NEPA analysis was performed for this action, referred to as saltwell pumping. The purpose and need does identify the need to manage and dispose of tank waste to reduce existing and potential future risks to the public, Site workers, and environment. The analyses provided in the EIS include a No Action alternative and the impacts analyzed for the alternative include potential future migration of waste to groundwater. Because DOE and Ecology believe the purpose and need for action is accurately presented in the Draft EIS, no modification to the document is warranted.

Comment Number 0043.01

Hanford Communities

Comment Radioactive tank waste is one of the most serious environmental risks on the Hanford site. The tanks continue to pose imminent safety risks to workers and the environment. These risks include the potential for catastrophic release through hydrogen gas flammability and groundwater contamination from leaking tanks. Our communities are frustrated with the lack of progress in getting the wastes out of the tanks and safely stored.

Response DOE and Ecology share the desire to move forward with remediation of the tanks at the earliest possible date and are implementing plans to accelerate remediation. In the mean time, DOE is performing numerous activities to place the tank farms in a controlled and stable condition and upgrade the regulatory compliance status of the tank farm system. (See Volume One, Section 3.4 and Appendix B for discussions of current and planned programs to manage the tank waste.)

L.3.0 DESCRIPTION AND COMPARISON OF ALTERNATIVES

L.3.1 INTRODUCTION

L.3.2 SITE AND WASTE DESCRIPTION

L.3.2.1 Tank Waste

Comment Number 0005.10

Swanson, John L.

Comment On another matter related to tank-by-tank inventory, on page A-2 it is said that "...tank farms were grouped together based on tank contents (inventory)..." Again, what data were used to perform such groupings? The inventory data presented in the EIS, and represented to be used therein, do not allow such groupings to be made. We thus have no way of knowing (or estimating) how valid these groupings are. I detect no special bias here, as I do in the consideration of the combined ex situ/in situ alternatives cases, but the story presented in the EIS should be complete and consistent.

Response DOE and Ecology acknowledge the concern expressed in the comment. The text has been modified to show that the tanks were grouped according to configuration, not according to content. This text modification appears in Volume Two, Appendix A, Section A.2.1.1.

Comment Number 0005.22

Swanson, John L.

Comment On page A-3, it appears to be stated as a fact that the K Basins sludges will be added to the tanks. This is news to me, and I do not believe that it is reflected in other portions of the EIS.

Response One proposed option for disposition of K Basin sludge identified by the 1996 K Basins EIS ROD is to remove and transfer the sludge to the DSTs. If implemented, the final disposition of this waste would be in accordance with the alternative implemented for tank waste management and disposal under the TWRS EIS. The Draft EIS included, in Appendix A, the K Basin sludge inventory as a potential source of new waste to be added to DSTs. K Basin sludges are discussed in Volume One, Section 3.4.1 and Volume Two, Appendix A, Section A.2.4.

Comment Number 0005.37

Swanson, John L.

Comment On page 3-11 it is said that "--new leaks are developing in these tanks at a rate of more than one a year." Are data available to support this statement, or is it an assumption that is stated as fact?

Response At the time the Safe Interim Storage (SIS) EIS was published, 67 SSTs were assumed to have leaked over the past 50 years. This number was used to support the statement that leaks would develop at a rate of more than one a year in the future. The saltwell pumping program, which involves removing liquids from the tanks, is expected to slow the rate of corrosion and substantially reduce future leaks (see Volume One, Section 3.4). Data are not available to accurately predict the number of new leaking tanks that will develop. The data identified above provide the best estimate available at the current time. Based on the saltwell pumping program to stabilize the SSTs and for the purposes of analysis in the TWRS EIS, no new leaks are assumed to occur during the 100-year administrative control period. The text of the EIS in Volume One, Section 3.2 has been modified to state that, "... new leaks are developing at a rate of one new tank known or assumed to have leaked per year."

Please refer to the response to Comment numbers 0072.70 (leak detection methods), and 0072.85 (predicted and anticipated future leaks).

Comment Number 0012.14

ODOE

Comment Tank Waste Characterization

The tank wastes are complex and poorly understood. The complex operating history of Hanford tanks has created a situation where the contents and character of the waste in every tank varies significantly from every other tank.

USDOE is working to characterize tank wastes. This should allow USDOE to narrow the uncertainties and mitigate severe hazards such as flammable gas generation. But, the data will not be detailed or accurate enough to ensure the risk assessments can accurately predict the fate of these wastes if they are left in the tanks.

Response The tank wastes are not well characterized on an individual tank basis, but an estimate of overall tank contents can be made. As noted in the EIS in Volume One, Section 3.2 and Volume Two, Appendix A, DOE has implemented a program to characterize tank waste on a tank-by-tank basis, which will be instrumental for resolving tank safety issues and final design activities for waste treatment. This program will aid in narrowing uncertainties regarding the waste in the tanks. However, DOE and Ecology believe that the existing historical data, laboratory data, and characterization reports provide an approximate estimate of tank contents from which the analysis of the tanks alternative can be completed to support the analysis and comparison of potential environmental and human health impact under National Environmental Protection Act (NEPA). The EIS acknowledges the uncertainties involved with the level of knowledge of the tank waste inventory and uses a conservative approach to assessing impacts based on the available data. This approach, known as bounding, provides an inventory of tank wastes that supports a risk assessment that DOE and Ecology believe fairly and objectively informs the decision makers and the public of the potential impacts associated with each alternative and support a comparative analysis of the alternatives. Tank-by-tank characterization will be needed to implement detailed design and operation of the TWRS action. If characterization data become available that are not bounded by the EIS analysis, DOE would complete an appropriate NEPA analysis to support analysis of environmental impacts and, if appropriate, alternatives that address the new data. See Volume Two, Appendix A for a discussion of tank inventory and Volume Five, Appendix K for a discussion of uncertainties.

Comment Number 0072.07

CTUIR

Comment In particular, two aspects are deficient within the TWRS-EIS. First, thorough characterization of the nature and composition of Hanford's chemically and physically complex tank wastes is in its infancy. It is clear that not enough information exists about these wastes within this EIS to adequately support retrieval and treatment needs, let alone facility design(s). If overall planning goals are not well understood in advance, the CTUIR SSRP asks, how will it be possible to design retrieval, treatment, and disposition systems that will meet protective waste management endstate and Tri-Party Agreement goals? This EIS should fit hand in hand with the Hanford sites overall guiding, framework document.

Response Though the characterization program for the tank waste is not complete, the EIS functions primarily as an environmental planning document, not as an engineering design document, and as such, will not include the complete details of programs like tank inventory and characterization or retrieval. As required by the Tri-Party Agreement, the tank waste characterization program will be completed September 1999. Assuming the tank waste characterization sample collection, analysis, and data interpretation must be finalized well in advance of the program, in addition to the reservoir of existing information, sufficient data would be available to support the detailed design of the transfer and retrieval systems, as well as of the treatment facilities. Where appropriate, the EIS incorporates such information by referencing the publicly available information on relevant topics. The locations of DOE Reading Rooms and information repositories containing publicly available information are given in the Summary, Section S.8. For example, the EIS contains references WHC 1995b, WHC 1995o, WHC 1994f, and WHC 1994g pertaining to tank contents and WHC 1994h pertaining to the characterization program. Tank retrieval and blending strategy is the subject of reference WHC 1995p. DOE and Ecology agree that it is necessary to ensure that tank waste remediation decisions are based on this EIS and are consistent with overall goals or designed endstates for the Hanford Site. To this end, the EIS describes the relationships among the alternatives and broader goals and policies, both nationwide and for the Hanford Site. For example, the relationship between the alternatives and tank closure is discussed in Volume One, Sections 3.3, 5.1-5.10, and 6.0. Further, Volume One, Section 6.0 describes the policy and regulatory background, including the Tri-Party Agreement, in relationship to the proposed action. Please refer to the response to Comment number 0012.14.

Comment Number 0072.14

CTUIR

Comment Considering the controversy surrounding the characterization of tank waste, the documentation of the contents of individual tanks and development of the "supertank" inventory should be better.

The entire tank waste characterization strategy needs to be examined and improved.

Response More complete knowledge of the tank contents would be preferable. At present, there is a program of tank characterization which, when completed, will provide information on the contents of each tank. Because that program of characterization is not completed, estimates of tank components were used in the EIS. The documentation of the inventory estimates that were used in the EIS is discussed in Volume Two, Section A.3.0 and in Volume Four,

Appendix E (Section E.1.1.3.1). The use of the super tank inventory is specifically discussed in Appendix A (Section A.3.3). The super tank inventory is intended to present the most conservative impacts from an accident so that the effects of accidents will not be underestimated. The super tank concentration of a chemical or radionuclide is the highest reported value that has been measured or calculated for that substance. This means that for assessing the impacts of an accident, a uniform inventory will be used for every accident scenario. For assessment of impacts, the use of this inventory data provides an equitable comparison of impacts. For the Final EIS, Appendix K (Volume Five) has been added to provide expanded information regarding uncertainties including inventory and accident. Please refer to the response to Comment numbers 0012.14 and 0072.07.

Comment Number 0072.67

CTUIR

Comment P 3-2: Sect. 3.2.1.2: Tank farm description: It is indicated here that 67 SSTs have leaked 2.3 million -3.4 million liters of liquids, it would be useful if there were a description on how this was calculated.

Response The estimate for the volume of waste that has leaked from the 67 known or assumed leaking SSTs was taken from the cited reference (Hanlon 1995). The referenced document, titled Tank Farm Surveillance and Waste Status Summary Report is one of a series of periodic reports that contains tank volume data as well as estimates and data for leak volumes from each of the known or assumed leaking SSTs. The methods used to estimate the volume of waste to have leaked varied by tank. The estimating method and the other parameters that impacted the assessment are contained in the footnotes to Table H-1 in the Waste Tank Summary Report for the month ending February 29, 1996 (Hanlon 1996).

Comment Number 0072.68

CTUIR

Comment P 3-4: PP 1: A vadose zone baseline characterization program could not possibly have determined the structure of the region underneath the tank farms given the amount of liquids presumed to have leaked and the large number of unknowns associated with the vadose zone points to an enormous amount of error in the ground water assumptions changing the future predictions on the rate of contaminate transport through the vadose zone will necessarily change the risk.

Response There are uncertainties and unknowns associated with the vadose zone modeling of rate and transport of contaminants from the tanks. Many of the uncertainties were addressed in Volume Four, Sections F.4.3.5 and F.3.4. The impact assessment modeling in Appendix F only addresses impacts from releases associated with TWRS remediation, not past leaks. Additional modeling was performed with evaluations provided in Volume Five, Appendix K that address potential transport mechanisms that may have been active during past leaks. Together, these evaluations and assessments provide the basis for developing appropriate mitigating measures. The response to Comment number 0012.15 contains an extensive discussion of vadose zone contamination issues, particularly uncertainty and subsurface geology.

Comment Number 0072.69

CTUIR

Comment P 3-7: PP 3: S 5: what is the precipitation process for the metal-salt compounds indicated here.

Response The sentence cited in the comment refers to the sludges in the tanks. Sludge is contained in a layer of water-insoluble chemicals that precipitated and settled to the bottom of the tank when the waste liquid from the processing plants was made basic by the addition of sodium hydroxide. Because of their reaction with sodium hydroxide, the sludge compounds are composed of primarily of metal hydroxides. Because the sludge composition may vary and other compounds may precipitate, the precipitate also is termed hydrous metal oxides.

Comment Number 0072.70

CTUIR

Comment P 3-11: PP 3: Bullet 1: How was the rate of leakage determined? Please explain how the control wells or the leak sensors are strategically placed.

Response The statement cited in this comment, taken from the SIS EIS, is as follows: "Removing saltwell liquid from older SSTs to reduce the likelihood of liquid waste escaping from corroded tanks into the environment. Many of these tanks have leaked, and new leaks are developing in these tanks at a rate of more than one per year" (DOE 1995i). This statement was intended to reflect the age, condition, and historical perspective of the SSTs. This statement also reflected the thinking at the time that since 67 SSTs were assumed or confirmed to leak, the leakage rate would continue at more than one per year in the future.

Several methods are used to find leaks. Starting in the early 1960's, vertical monitoring wells, called drywells, were drilled around the SSTs. These wells are called drywells because they do not reach the water table. Approximately 760 drywells, located around the SSTs, are used to measure increases in radiation in the ground caused by tank leakage. Multiple drywells are located around the perimeter of the tanks in order to monitor around the tanks. A second way to detect leaks is to use a lateral drywell. This is a drywell drilled horizontally underneath a tank where the radiation in the soil can be measured by a detection probe. A third way to detect leaks is to lower radiation probes into liquid observation wells inside the tank and measure the radiation as a way to identify the level of liquid. By comparing the current liquid level with the last recorded level, a large leak can be detected. Detecting leaks in SSTs is an imprecise activity. As all tanks continue to age, the number of leaking tanks will likely increase. Please refer to the response to Comment number 0005.37.

Comment Number 0072.71

CTUIR

Comment P 3-11: PP 5: Bullet 3: In the event of loss of institutional control, and the loss of the mixer pump in 101-SY, could the microcrystalline mat reform much stronger and thicker, resulting in greater entrapment of hydrogen and other flammable gases?

Response The loss of institutional control, as an assumed event, would result in the termination of continuing operations at the tank farms. The loss of institutional control would mean that the day-to-day activities concerned with management of the tank wastes would no longer continue. This would mean that the mitigative measures currently being applied to the tank wastes would no longer be performed including the use of the mixer pump in tank 101-SY. The tank would revert to its condition before the mixer pump was installed. Whether the sludge layer would reform much stronger and thicker is unknown; however, this possibility cannot be ruled out. A discussion of potential remediation and post-remediation accidents is contained in Volume One, Section 5.12 and Volume Three, Appendix E. Please also refer to the response to Comment numbers 0040.02 and 0040.03 for more information related to administrative controls and the response to Comment number 0072.80 for discussions of the reason and basis for assuming a 100-year administrative control period.

Hydrogen and other flammable gas deflagration accidents were analyzed in the EIS. For post-remediation accidents, an analysis of the flammable gas deflagration accident, among others, determined that a seismic event would result in bounding case accident conditions and therefore the post-remediation accident presented in Volume One, Section 5.12 is the seismic event.

Comment Number 0072.72

CTUIR

Comment P 3-13: PP 1: This is the first notation on complexing of tank waste, please include a discussion on exactly what is meant by complexing waste.

Response The subject discussion regarding the SIS EIS ROD is provided in the EIS to inform the reader of planned activities to address urgent safety or regulatory compliance issues. The discussion of complexed and noncomplexed waste with respect to tank 102-SY was presented in the SIS EIS (DOE 1995i). A definition of complexed and noncomplexed waste is also provided in the glossary of the TWRS EIS. Because the information requested in the comment was included in the Draft EIS, no modification to the document is warranted. Please also see the response to Comment number 0072.170 for more information about complexed waste.

Comment Number 0072.73

CTUIR

Comment P 3-13: PP 2: S 3: What part if any has the DOE done to insure that the affected tribes are involved and kept up to date with the transfer of responsibility, accountability, and liability?

Response The phased approach to implementation of the alternatives is discussed in Volume One, Section 3.3. Contracting strategy is not an issue addressed in the EIS. However, DOE recognizes the importance of maintaining an interactive relationship with the affected Tribes. Informal discussions as well as meaningful consultation and cooperation result in better understanding of important cleanup issues.

In the developing months of the privatization effort (Spring/Summer 1995), invitations were issued to the affected Tribes to present the initially envisioned concept. Letters and follow-up communiqués were issued to J.R. Wilkinson, Hanford Program, Confederated Tribes of the Umatilla Indian Reservation (CTUIR); Donna Powaukee, Environmental Restoration and Waste Management (ERWM) Manager, Nez Perce Tribe; and Russell Jim, Confederated Tribes and Bands of the Yakima Indian Nation. Of the invitations, only the Nez Perce requested and participated in a discussion of the project with a DOE representative and staff. Follow up correspondence addressing questions and concerns was issued August 1995.

Following issuance of the TWRS Request for Proposals (RFP) (February 1996), a request was made for a copy by Joseph H. Richards, Environmental Compliance Auditor, CTUIR on February 23. The following day, the document was forwarded to him.

Progress reports and status updates are routinely provided to the Hanford Advisory Board, which has Tribal representation. This is not to suggest that interactions with the Board substitutes, or may be conducted in lieu of, both formal and informal interactions with the Tribes. DOE encourages such interactions and welcomes opportunities to discuss important cleanup activities with the Tribes. An in-depth discussion of the Tribal consultation process for the TWRS EIS is presented in the response to Comment number 0072.252.

Comment Number 0072.74

CTUIR

Comment P 3-13: PP 2: S 7: The CTUIR agrees that the plan for privatization is subject to the final record of decision of the TWRS EIS.

Response The TWRS EIS ROD will document the decision for how to remediate the tank waste. DOE intent in preparing the schedules for the TWRS EIS and the award of Phase 1a contracts was to have the EIS ROD completed prior to the contract award. To ensure that the award of contract could proceed in the event of a schedule disruption to the EIS ROD, DOE clarified in the final RFP that action under the contract would be contingent on the outcome of the TWRS EIS ROD, a decision which would be considering other alternatives and, if chosen, might necessitate renegotiating or voiding the contract award.

DOE NEPA Implementing Procedures (10 CFR 1021) require DOE to "complete its NEPA review for each DOE proposal before making a decision on the proposal (e.g., normally in advance of, and for use in reaching, a decision to proceed with detailed design)" (10 CFR 1021.210 [b]). The November 1995 draft RFP indicates that Phase 1a is intended as a "development period to establish the technical, operations, regulatory, and financial elements required in privatized facilities." It is only in Phase 1b that the selected contractors will provide detailed, complete design, and be authorized to proceed with construction and operations. These circumstances and requirements comply with NEPA procedures that provide for submittal of environmental data and analysis by offerors and incorporation of an environmental synopsis of that data and analysis in any NEPA document prepared (10 CFR 1021.216 [h]), as long as the actions taken prior to beginning detailed design do not "have an adverse environmental impact" or "limit the choice of reasonable alternatives." Based on the planned Phase 1 approach of splitting the action into two subphases, DOE would be able to proceed with Phase 1a (conceptual design) prior to completion of the TWRS EIS ROD and be within the intent of NEPA. However, the TWRS EIS ROD would be required prior to the anticipated April 1998 award of Phase 1b contracts.

Comment Number 0072.80

CTUIR

Comment P 3-21/22: while it is acknowledged that NEPA requires that an EIS includes a no-action alternative, it should also be acknowledged that leaving leaking tanks violates several laws, regulations, and statutes. Also, no-action would not necessarily be a "continue the current waste 'management' program." It would more likely be a walk-away situation where institutional controls fail.

Response The No Action alternative would result in failure to comply with Federal and State laws and regulations. This information is presented in Volume One, Section 6.2 and in the Summary, Section S.7. EIS Sections S.7, 3.4, and 6.2 describe the Federal and State compliance issues applicable to the No Action alternative. DOE guidance on NEPA requires that EIS alternatives be addressed regardless of "conflict with lawfully established requirements" (DOE 1993d). DOE is required to identify the laws and regulations that apply to each alternative and indicate whether the alternative, if selected, would comply with applicable laws and regulations (40 CFR 1502.2d). Please refer to the response to Comment numbers 0093.02 and 0072.52.

Guidance on the implementation of NEPA Council on Environmental Quality (CEQ) Memorandum to Agencies: Forty Most Asked Questions Concerning CEQ's National Environmental Policy Act Regulations states the following.

Section 1502.14(d) requires the alternatives analysis in the EIS to "include the alternative of no action." There are two distinct interpretations of "no action" that must be considered, depending on the nature of the proposal being evaluated. The first situation might involve an action such as updating a land management plan where ongoing programs initiated under existing legislation and regulations will continue, even as new plans are developed. In these cases "no action" is "no change" from current management direction or level of management intensity. To construct an alternative that is based on no management at all would be useless academic exercise. Therefore, the "no action" alternative may be thought of in terms of continuing with the present course of action until that action is changed.

In the case of the TWRS program, there is an ongoing program to safely manage the tank waste that would continue under any reasonable scenario for the 100-year administrative control period. For this EIS, no action is assumed to be no effort other than the safe management practices currently conducted. The "walk-away" alternative was not evaluated, because it would present an imminent danger to human health and the environment and would be a useless academic exercise.

Comment Number 0072.81

CTUIR

Comment P 3-24: last paragraph: exactly what does "enough waste would be remediated"? Does this mean that the characterization of the tanks, tank farms, intra-tank, tank mixtures, solubility mixtures would be done on a pilot scale in ten years on an order of magnitude to justify 1.6 billion dollars of set-aside moneys. Is this amount of money justified in terms of removal of tank waste, lowering of risk, characterization, and achieving Tri-Party Agreement milestones.

Response The referenced language means that a sufficient quantity of waste would be remediated during Phase 1 to prove that remediation would be effective for the entire remediation program. The sentence was modified in Volume One, Section 3.3 as follows for clarification. "A sufficient quantity of a variety of tank waste types would be processed to demonstrate the effectiveness of the process and to provide the necessary data to design a full-scale facility." Please refer to the response to Comment number 0005.38.

Comment Number 0072.168

CTUIR

Comment P A-1: Sect. A.2.1: It is appropriate to list the estimated radionuclide and non-radionuclide inventory for each tank or tank farm for comparison.

Response Please refer to the response to Comment numbers 0012.14 and 0072.07. The information requested in the comment is a level of detail that DOE and Ecology believe is not necessary for meaningful discrimination among the alternatives.

Comment Number 0072.169

CTUIR

Comment P B-8: What is actually in the miscellaneous underground storage tanks? The characteristics of an expected waste indicates a need for a comprehensive characterization, even if the total combined inventory of MUSTs volumes is less than one half of one percent of the total tank inventory.

Response Please refer to the response to Comment numbers 0012.14 and 0072.07 for issues related to tank waste characterization. Please also refer to Comment number 0072.99 for MUST content information. The information requested in the comment is a level of detail that DOE and Ecology believe is not necessary for meaningful discrimination among the alternatives.

Comment Number 0072.170

CTUIR

Comment P B-10: What are the characteristics of concentrated complexant waste?

Response Concentrated complexant waste is the concentrated aqueous raffinate from strontium-90 liquid-liquid extraction operations performed in the 1960's and 1970's. This waste is a component of the wastes in the AN and SY tank farms, although some is in the DSTs because of saltwell pumping. It is characterized by a high organic content including the complexants ethylenediaminetetraacetic acid (EDTA), citric acid, and hydroxyethylenediaminetriacetic acid (HEDTA).

Comment Number 0072.171

CTUIR

Comment P B-12: PP3: Please explain what is meant by 'have or may have' greater than 50,000 gal of drainable liquid.

Response The section describes the installation of liquid observation wells in the tanks. The criteria for installation is the presence, or suggested presence, of at least 50,000 gallons of drainable liquid. The criteria retains the provisional phrase 'have or may have' because the exact quantity of liquid remaining in the saltcake will not be known until the liquid has been removed and its volume is measured.

Comment Number 0072.172

CTUIR

Comment P B-12: PP4: How many and how often are radiation measurements taken in the drywells?

Response Radiation measurements taken in the drywells are included in the discussion of ongoing tank monitoring and maintenance activities and are one of the methods used to monitor for tank leaks in Volume One, Section 3.2 and Volume Two, Appendix B. Two drywells at two SSTs (tanks 241-C-105 and 241-C-106) are currently monitored monthly by gamma radiation sensors. The remaining tanks are monitored by the TWRS program periodically based on the need to detect potential new leaks and/or to document the extent and nature of past leaks.

Comment Number 0072.173

CTUIR

Comment P B-16: PP5: Please re-do this paragraph. It is confusing and could be better written. For example, the description of the majority of radioactive elements in the sludges needs to be expanded and an indication needs to be made whether the sludges are at the bottom of the tanks or elsewhere.

Response The referenced paragraph provides a generic description or overview of the waste in numerous tanks rather than in individual tanks. The three types of waste (i.e., liquid, sludges, and saltcake) are present in the individual tanks in varying combinations and proportions. For example, sludges may be located at the bottom of the tank, caked along the side of the tank, or both. Although there is a considerable amount of tank waste inventory available from process records and past sampling activities, this information is not considered adequate to characterize the waste in individual tanks. However, DOE is actively involved in an ongoing waste characterization program that is using waste sampling and analysis, in situ measurements, monitoring, surveillance, and waste behavior modeling to provide more detailed and accurate characterization data for the content of individual tanks. Current agreements among DOE, Ecology, and EPA require that all characterization reports be issued by September 1999. Volume Two, Sections A.2 and A.3 present additional information on the tank inventory data including the estimated radionuclide inventory for SSTs and DSTs, ongoing tank characterization programs, and tank inventory data accuracy and its effect on the EIS. Please refer to the response to Comment numbers 0012.14 and 0072.07. Because the information requested in the comment was included in the Draft EIS, no modification to the document is warranted.

Comment Number 0072.174

CTUIR

Comment P B-18: PP3: The statement, "upgrade the regulatory compliance status" implies that the DOE may not be in compliance even after they complete the SIS EIS activities.

Response In the context of the TWRS EIS alternatives, the referenced statement regarding the SIS EIS refers only to the compliance status of the cross-site transfer portion of TWRS. Installing the cross-site transfer pipeline would comply with applicable regulations whereas the existing cross-site transfer pipeline does not. It is DOE policy to conduct its operations in an environmentally safe and sound manner in compliance with applicable environmental statutes, regulations, standards, and the Tri-Party Agreement. Routine operations at the tank farms include monitoring and maintaining the regulatory status, and operations and maintenance of facilities and equipment. However, upgrading the regulatory compliance status as part of the process of placing the tank farms in a controlled, stable condition involves multiple and continuing activities, particularly as facilities age. The EIS addresses upgrades specific to the waste transfer system (Volume Two, Section B.3). The cross-site transfer system and upgrades under the TWRS EIS are actions identified in the Tri-Party Agreement Resource Conservation and Recovery Act (RCRA) compliance provisions. Volume One, Sections 1.1 and 3.2 provide additional information regarding how the SIS EIS and TWRS are interrelated. Volume One, Section 6.0 describes the statutory and regulatory requirements potentially applicable to TWRS.

Comment Number 0072.175

CTUIR

Comment P B-20: PP1: If the goal of privatization has a component that transfers a share of accountability and liability to industry, have the affected Tribes been properly notified and consulted regarding this? If so, when and with whom were the notifications and consultations addressed to?

Response Please refer to the response to Comment number 0072.73.

Comment Number 0072.176

CTUIR

Comment P B-20: PP2: Once again the statement "upgrade the regulatory compliance status" indicates that even after the current planned upgrades the tank farms may not be in compliance. The planned upgrades listed including instrumentation, ventilation, and electricity is supposed to place the tank farms in a controlled stable condition. Please bring forth a discussion on how these three upgrades will accomplish this.

Response DOE and Ecology acknowledge that even after the current planned upgrades, the tank farms may not be in full compliance. However the upgrades are required by the Tri-Party Agreement which is the RCRA enforcement agreement among DOE, Ecology, and EPA. The upgrades when completed along with other projects such as the saltwell pumping program will result in the attainment of controlled onsite conditions for the SSTs. Upgrades to the instrumentation, ventilation, and electrical systems are not included in the scope of this EIS; however, these activities are the subject of other NEPA documents. Please refer to the response to Comment number 0072.174. Because the information contained in the Draft EIS is correct, no change to the text was made.

Comment Number 0077.01

ODOE

Comment More than a million gallons of high-level wastes have already leaked from these tanks, threatening the aquifer and the groundwater. Plutonium and americium from one tank leak at Hanford have migrated over 100 feet through the soil and may have reached the groundwater. A third of the tanks have been placed on a "watch" list because of the danger of explosions.

Response DOE and Ecology concur the magnitude and complexity of the tank waste issues that constitute the purposes and need for the TWRS action. DOE must implement decisions to manage and dispose of tank waste to reduce existing and potential future risk to the public, Site workers, and the environment. The EIS includes an analysis of alternatives to manage and dispose of tank waste. The analysis of impacts includes potential impacts to groundwater in Volume One, Section 5.2 and Volume Four, Appendix F; remediation and post remediation health impacts in Volume One, Section 5.11 and Volume Three, Appendix D; and remediation and post-remediation accidents, including the risk of explosions, in Volume One, Section 5.11 and Volume Four, Appendix E. The cumulative impacts of past leaks and TWRS actions are presented in Volume One, Section 5.13. Please refer to the response to Comment numbers 0072.61 (estimates of tank volume thought not to have leaked), 0072.63 (leak volume thought to be cooling water) and 0072.67 (leak volume estimating methods) for more information about tank leaks. Current methods used to detect leaks are discussed in the response to Comment number 0072.70.

Comment Number 0089.10

Nez Perce Tribe ERWM

Comment Page A-13, Table A.2.1.2

The Table delineates the soluble and insoluble portions of chemical species. This information is useful, but it would be helpful to see a listing of the chemical compounds rather than just anions and cations listed separately. A better understanding of tank chemical processes is possible with a listing of chemical compounds.

Response DOE and Ecology concur that more complete knowledge of the tank contents, including the exact nature of the chemical compounds would be advantageous. At present, there is a program of tank characterization which, when completed, will provide greater depth of knowledge as to the contents of each tank. Because that program of characterization is not yet completed, estimates of tank components were used in the EIS. Information on the chemical compounds within the tanks is limited. The inventory estimate provided for use in the EIS (WHC 1995d) gives the chemical species in their ionic form. For purposes of assessing impacts from the release of the tank contents, the use of the ionic forms was sufficient. Please refer to the response to Comment numbers 0012.14 and 0072.07. The information requested in the comment is a level of detail that DOE and Ecology believe is not necessary for meaningful discrimination among the alternatives.

L.3.3 DEVELOPMENT OF ALTERNATIVES

L.3.3.1 Tank Waste

Comment Number 0005.17

Swanson, John L.

Comment The fact that tank closure is not included in the analysis seems to me to be a serious deficiency. The statement on S-15 that "Closure is not within the scope of this EIS because there is insufficient information available concerning the amount of contamination to be remediated." seems to me to be a cop-out. You go on to base the analysis that you do on an assumed 1 percent left in the tanks; data given on page S-7 indicate that 0.5 percent of the waste activity has been released or leaked to the ground. Isn't an estimate of 1.5 percent of the contamination to be remediated during closure sufficient information on which to base an analysis? (It is certainly as close an estimate as many of those used in the analyses that were done in this draft).

Response Closure is not within the scope of this EIS because information, such as the nature and extent of vadose zone and groundwater contamination to identify and analyze reasonable closure alternatives is insufficient to support an evaluation of closure alternatives. The Notice of Intent to prepare the TWRS EIS stated, "The impacts of closure cannot be meaningfully evaluated at this time. DOE will conduct an appropriate NEPA review, such as an EIS, to support tank closure in the future" (59 FR 4052). However, some of the decisions to be made concerning how to dispose of tank waste may impact future decisions on closure, so the EIS provides information on how tank waste remediation and closure are interrelated. A single and consistent method of closure was assumed for all alternatives to allow for a meaningful comparison of the alternatives. The closure method used for purposes of analysis was closure as a landfill, which includes filling the tanks and placing an earthen surface barrier over the tanks after remediation is complete. For a discussion of how closure was addressed within the EIS, see Volume One, Section 3.3.

Specific and detailed information on the distribution of contaminants from tank leaks and past practice activities is not available in sufficient detail to provide a meaningful comparison of impacts. When sufficient information is available to evaluate the closure options, DOE will submit a final closure plan to Ecology for review and approval, and an appropriate NEPA analysis will be completed. An extensive discussion of closure and issues related to closure is presented in Comment number 0072.08.

Because the analysis requested in the comment is not within the scope of the EIS, no modification to the document is warranted.

Comment Number 0005.18

Swanson, John L.

Comment The assumptions of a) 1 percent of the contaminants (including the water soluble ones) left in the tanks and b) no attempt to immobilize this residual, lead to a lack of discrimination risk is dominated (by a factor of 100) by the risk of the non-immobilized 1 percent assumed to be left in the tanks. This is a classic case of "assumption driving the conclusion." For the purposes of this EIS, wouldn't it be better to assume a closure approach that would allow differences in the considered alternatives to apparent? It would be strange to me if the same "public" that drove out grout as a LLW form because of perceived contaminant release problems would be willing to accept a situation where the overall release is 100 times greater than that from their preferred waste form because something was not done to immobilize the waste left in the tanks (or to rinse out more than 99 percent of the water-soluble contaminants).

Response As stated in Volume One, Section 3.4, the calculations in the EIS are based on the assumption that the waste residual would be composed of the average tank contents, which is a very conservative assumption because the liquids used to retrieve the waste would remove a high percentage of water-soluble contaminants. The water-soluble contaminants are those that contribute to long-term risks because they can be transported over the long term into the groundwater. In response to the issue raised in this comment and others, calculations have been performed and presented in the Final EIS based on a less conservative content of the residuals where most of the water-soluble contaminants are removed. This provides both a bounding and nominal calculation of risks and provides the public and decision makers with greater information concerning long-term risks. This new information is contained in Section 3.4, 5.2 and Appendix F of the Final EIS. For more information regarding closure assumptions and how closure was addressed in the EIS, please refer to the response to Comment numbers 0005.17 and 0072.08 and Volume One, Section 3.3.

Comment Number 0005.26

Swanson, John L.

Comment Page A-7 contains a statement that conservative values of distribution coefficients"--would ensure that travel times of contaminants were at the upper bound--." Shouldn't that be LOWER bound?

Response The distribution coefficient is defined in such a manner that the constituents with the lowest distribution coefficients are those that travel with a greater velocity. The higher the distribution coefficient, the greater the resistance to movement. Therefore, the text is correct as written.

Comment Number 0005.38

Swanson, John L.

Comment At the bottom of page 3-24 and top of page 3-25, it is said that the Phased Implementation approach Phase 1 would remediate enough waste to prove that the many waste types in the tanks could be remediated effectively. This sounds good, but for it to be true you must have a different Phase 1 in mind that the Privatization Phase 1, which will prove essentially nothing about the pretreatment of SST sludges. (On page 3-92 I find "The waste processed during Phase 1 COULD (emphasis added) also include selected SST waste." This is a much different slant than the statement on page 3-24,-25).

Response The referenced text in Volume One, Section 3.3 has been revised to be less encompassing. It is DOE's intent to process enough different feedstocks (e.g., waste types and compositions) during Phase 1 to demonstrate the treatment processes before implementing Phase 2. Different feedstocks processed during Phase 1 would be expected to demonstrate maximum facility thruput, treatment of high cesium level waste, and treatment of organically complexed TRU and Strontium-90 waste. It is believed that by treating the different waste feedstocks identified during Phase 1, the majority of the waste types present in the tanks, including the SST sludges, would be adequately demonstrated to proceed with Phase 2. As explained in Volume One, Section 3.3, the contracting strategy known as privatization is not within the scope of the EIS. Please refer to the response to Comment number 0072.81.

Comment Number 0022.02

Sims, Lynn

Comment In terms of all human history we are treading on unchartered ground. Here we are confronted with a terrible cold war legacy which threatens our lives and environment. We are engaged in a monumentally serious and expensive undertaking which projects itself far into the future. Our current technology is not totally adequate, but we are morally obligated to do the very best we can NOW and not pass this dilemma to future generations.

We do know we are in this situation because of poor management and inadequate long-term planning during the production years. We do not wish to repeat these mistakes and impose disastrous results upon future generations by shortcomings in clean up decision making now.

Response The magnitude and potential impact of the tank waste are among the most extensive of the Cold War legacies. Moreover, the type and volume of waste and the scale of the technologies required for retrieval, treatment, and disposal are unprecedented. The waste poses substantial potential risks to human health and the environment. The costs for implementing any of the alternatives are substantial, and all alternatives would involve tasks that would continue for many years into the future.

It is for these reasons, among others, the Federal agencies are required to complete an EIS before decisions are made and before actions are taken. This allows decision makers and the public to be aware of the potential environmental consequences of the proposed action and ways to mitigate those impacts and for the public to be involved in decisions that affect the quality of the human environment.

Comment Number 0072.05

CTUIR

Comment The idea of NEPA is to identify and assess the full range of available options and technologies to address an issue -- in this case, the safe, effective, and protective treatment and disposition of dangerous Hanford high-level radioactive and hazardous mixed tank wastes. The current TWRS-EIS focuses only on retrieval of wastes and the explicit thermal treatment option of vitrification. Moreover, although 'closure' is not within the scope of the TWRS-EIS, a number of identified alternatives and considerable discussion throughout the EIS either pre-determine or limit ultimate closure options. The CTUIR SSRP, as a result of their interactions with other federal agencies, have noted that other potentially applicable technologies for tank waste treatment exist. A more broad range of applicable and feasible alternative treatment/disposal technologies needs to be systematically assessed with our consultation.

Additionally, NEPA requires a thorough scoping and assessment of key issues, a systematic set of screening or decision criteria, and a comprehensive consideration of a range of technological (or other) approaches to reach the desired endstate. The current TWRS-EIS examines only a limited set of treatment/disposal options and therefore cannot possibly compare the full spectrum of risks, costs, and benefits of alternative treatment/disposal options.

The Tank Waste Task Force (TWTF) identified that a "portfolio" of options for tank waste treatment and disposition should actively be explored, analyzed, and maintained for contingency planning purposes. The sheer complexity, diversity, and volume of Hanford tank wastes should intuitively mandate such an option-as-necessary-and-available approach.

Response A wide range of potentially applicable technologies exists for treating tank waste. One challenge was to eliminate from consideration technologies that were not viable and develop a range of reasonable alternatives for detailed analysis and presentation in the TWRS EIS. This discussion describes how the alternatives were developed.

There is a distinction between technologies and alternatives. Technologies are specific processes (e.g., cesium ion exchange) that relate to a component (e.g., retrieval or treatment) of an alternative. Alternatives include a set of technologies, or building blocks, that have been engineered to work together, forming complete systems for accomplishing the purpose and need for action. Alternatives are made up of a number of technologies linked together.

The evaluation of potential technologies for inclusion in the TWRS EIS began with a review of available technologies from a variety of sources including the Tank Waste Technical Options Report (Boomer et al. 1993), the Tri-Party

Agreement (Ecology et al. 1994), Hanford Defense Waste EIS (DOE 1987), and the engineering data packages prepared by the Site Management and Operations contractor (WHC 1995a, c, e, f, g, h, i, j, and h).

The first step in developing alternatives was to screen out technologies that were not viable. The full range of available technologies for each component of the proposed action was evaluated, and technologies that were not viable were eliminated from further consideration. The technologies eliminated by this screening process are described in Volume One, Section 3.8 and Volume Two, Appendix C.

After rejecting technologies that were not viable, a large number of potential technologies remained for inclusion in the EIS. It would not be practicable to develop alternatives that include all of the potential combinations of technologies. In accordance with NEPA, representative alternatives were developed for detailed analysis to bound the full range of reasonable alternatives (DOE 1993d). Upper, lower, and intermediate bounding alternatives were developed in terms of cost, risk, and technologies for the two primary decisions that affect environmental impacts: the amount of waste to be retrieved from the tanks and the degree of separations of retrieved waste into HLW and LAW. The full range of applicable technologies and alternatives therefore is included in the EIS.

Similar to the approach used by the Tank Waste Task Force, representative alternatives were developed for detailed analysis in the EIS. There are many other viable technologies for individual components of the alternatives that could not be included. These technologies are included in Volume Two, Appendix B and constitute the "portfolio" of options that could be substituted for one of the technologies that is included in an alternative without a substantial change in the impacts of that alternative. An evaluation was performed for each of the technologies identified in Appendix B. Where there would be changes in impacts, the changes are discussed in Appendix B. The level of analysis was dependent on the magnitude of the change on impacts.

The alternatives developed for presentation in the EIS were chosen to be representative of many of the possible variations of the alternative. The design information for all alternatives is at an early planning stage, and the details of the alternative that ultimately is selected and implemented may change as the design process matures. Therefore, the alternatives are intended to represent an overall plan for remediation at a level of detail sufficient for impact analysis and alternative comparisons.

DOE and Ecology are not aware of any other viable technology EIS for tank waste treatment. Please refer to the response to Comment numbers 0005.17 and 0072.08 for a discussion of the reasons closure was not addressed in the EIS.

Comment Number 0072.08

CTUIR

Comment The second major deficient factor is closure, both of waste treatment/disposal facilities and the tank farms themselves. The resolution of the tank waste issues are complex, time-transgressive, and fundamentally impact life-cycle costs. Closure issues, while not within the scope of this EIS, are essential to comprehensive planning for both waste retrieval and treatment from the tank farms. Additionally, closure will significantly impact long-term waste management and land consumption requirements on Hanford's Central Plateau -- a directly connected action which must be specifically assessed and coordinated with the CTUIR SSRP. A specific and incremental plan must be developed to accomplish safe and effective long-term waste management, and this necessarily requires a known endstate goal.

Response The final disposition of the tanks and associated equipment and the remediation of contaminated soil and groundwater associated with leaks from the tanks is a process called closure. Closure is not within the scope of this EIS because there is insufficient information concerning the amount of contamination to be remediated. The amount and type of waste that ultimately remains in the tanks after remediation may also affect closure decisions. The Notice of Intent to prepare the TWRS EIS stated that: "The impacts of closure cannot be meaningfully evaluated at this time. DOE will conduct an appropriate NEPA review, such as an EIS to support tank closure, in the future (59 FR 4052)." However, some of the decisions made concerning how to treat and dispose of tank waste may impact future decisions on closure, so the tank waste alternatives provide information on how tank waste remediation and closure are interrelated. Closure options and assumptions are discussed in Volume One, Section 3.3.1 of the EIS.

Under the Tri-Party Agreement, the tanks are classified as hazardous waste management units that eventually would be closed under the State Dangerous Waste Regulations (WAC 173-303) and the requirements of the Tri-Party Agreement. Three options exist for closure of the tanks. The first option is clean closure, which would involve the removal of all contaminants from the tanks and associated equipment, soil, and groundwater until natural background levels or health-based standards are achieved. The second option is modified closure, which would involve a variety of closure methods and would require periodic (at least once after 5 years) assessments to determine if the modified closure requirements were met. If modified closure requirements were not being met, additional remediation would be performed. Modified closure is a method specific to the Hanford Site Permit under the State Dangerous Waste Regulations (WAC 173-303). The third option is closure as a landfill, which would involve leaving some waste in place with corrective action taken for contaminated soil and groundwater performed under postclosure requirements. This type of closure usually involves the construction of a low permeability cover over the contaminated media to reduce water infiltration and prevent inadvertent human intrusion. When sufficient information is available to evaluate the closure options, DOE will submit a final closure plan to Ecology for review and approval and an appropriate NEPA analysis will be completed.

Although sufficient information is not available to make final decisions on closure, some of the alternatives affect future closure decisions, so information is provided to allow the public and decision makers to understand how the alternatives would be interrelated with future closure of the tank farm system. For example, some of the alternatives addressed in the EIS involve removing most of the waste from the tanks (the ex situ alternatives) and would not substantially affect options for future closure decisions. Conversely, some of the alternatives do not involve removing the waste from the tanks (the in situ alternatives) but rather, would treat and dispose of the waste in the tanks. These alternatives include placing a low permeability cover over the tank farms to reduce water infiltration and prevent inadvertent human intrusion (e.g., Hanford Barrier). This would be considered closure as a landfill. Clean closure would be precluded by implementing one of the in situ alternatives. However, this would not address remediation of the soil and groundwater previously contaminated, so it would not represent complete closure of the tank farms. Therefore, the in situ alternatives would preclude clean closure of the tanks. The ex situ alternatives would not preclude any closure alternative. The decisions on closure will be made in the future when sufficient information is available.

For purposes of comparing the alternatives, a single and consistent method of closure was assumed for all of the alternatives. Closure as a landfill was chosen as the representative closure method for purposes of analysis and is included in all of the alternatives (except the No Action and Long-Term Management alternatives). This does not mean that closure as a landfill is proposed or necessarily would be selected in the future. It is included to allow a meaningful comparison of the in situ and ex situ alternatives and to provide information to the public and the decision makers of the total cost and impacts of final restoration of the Site.

Because decisions on closure cannot be made at this time but are interrelated with decisions to be made on remediation of the tank waste, the EIS presents an analysis of impacts with and without closure in Section 5.0. In each applicable subsection of Section 5.0, the impacts of the activities associated with remediating the waste are presented first. This is followed by the presentation of the combined impacts of remediating the tank waste and closing the tank farms by closure as a landfill. This provides the public and the decision makers with information on the impacts of the issues that are ripe for decision making (remediation of the tank waste) and information on the total project impacts (remediation and closure) as well as how they may be interrelated with the decisions on remediation of the tank waste.

A comprehensive land-use plan (CLUP) is being developed for the Hanford Site, and another NEPA analysis will be prepared on the tank farm closure. The CTUIR will be consulted during the preparation of both documents.

Comment Number 0072.50

CTUIR

Comment It is not clear whether any of the alternatives will allow clean closure, and none of the alternatives include removal of tanks (or support structures).

Response Please refer to Comment number 0072.08 for a discussion of the relationship between the TWRS EIS and future closure decisions. Selection of the No Action, Long-Term Management, In Situ Fill and Cap, In Situ Vitrification (ISV), or Ex Situ/In Situ Combination alternatives would preclude clean closure. The extensive retrieval alternatives would not preclude any closure option. The discussion of closure in Volume One, Section 3.3 was modified to identify which alternatives would preclude clean closure.

Comment Number 0072.51

CTUIR

Comment There is an ongoing problem with failure to define retrieval and closure goals before retrieval is begun. At present, the action plan is to attempt retrieval, and then determine how well we did and therefore whether the tank farms will be closed as a landfill or clean closed.

Response DOE has plans to perform retrieval tests. The project is called The Hanford Tank Initiative and is discussed in Volume One, Section 3.2 of the Final EIS. The information gained from this program will provide data on the effectiveness of a variety of retrieval techniques. The waste retrieval goal is discussed in Volume One, Section 3.4 of the EIS. Please refer to the response to Comment number 0072.08 for a discussion of the relationship between NEPA requirements, the TWRS EIS alternatives, and closure. If an ex situ alternative is selected, the success of retrieval would be a factor in determining the type of closure performed.

Comment Number 0072.75

CTUIR

Comment P 3-18: PP 6: Because closure is not in the scope of this EIS, the CTUIR feels that this EIS is incomplete and actions to correct this should be taken, for example, by designing how a closure plan should be incorporated into this EIS.

Response Please refer to the response Comment number 0005.18 for a discussion of the reasons why tank farm closure alternatives cannot be analyzed at this time. The response to Comment number 0072.08 discusses the relationship between this EIS and future closure options. This response contains a discussion of the relationship between NEPA requirements, the tank waste remedial alternatives

evaluated, and related closure issues. DOE, in the Notice of Intent to propose this TWRS EIS, has committed to complete the appropriate NEPA analysis when data become available to support the analysis. The Tri-Party Agreement contains milestones relative to the preparation and approval of a closure plan for the SSTs.

Comment Number 0072.76

CTUIR

Comment P 3-20: PP 1: The CTUIR SSRP technical staff states that anything less than clean closure would result in excess risk to tribal members.

Response DOE and Ecology acknowledge the preference expressed in the comment and will consider this and other concerns when selecting the final action for TWRS waste. Closure will be addressed in a future NEPA analysis when sufficient data are available to provide a meaningful comparison of closure alternatives. Please refer to the response to Comment numbers 0072.08 and 0072.50.

Comment Number 0072.77

CTUIR

Comment P 3-20: PP 2: For the purposes of comparing the alternatives and as not to preclude ruling out any closure alternatives, the clean closure is, should, and will be replaced in all the following alternatives sections. Additionally it is impossible to do a meaningful comparison between in situ and ex situ alternatives.

Response Tank farm closure was presented in the EIS as a hypothetical closure scenario to demonstrate the relationship between remediation and closure to the public and the decision makers and so in situ and ex situ alternatives could be equitably compared. Using closure as a landfill as the hypothetical closure scenario does not mean that it has been or will be selected for implementation. Tank farm closure will be addressed in a future NEPA analysis when sufficient data are available to provide a meaningful comparison of closure alternatives. Please refer to the response to Comment number 0072.08 for a discussion of the reasons closure alternatives are not appropriate for inclusion in the EIS.

Comment Number 0072.78

CTUIR

Comment P 3-20: PP 3: S 4 : Environmental restoration, waste management, and remediation together which define clean-up have been and are ripe for tank farm decision making. You can not separate a removal process from a closure process and plan for privatization without truly considering the future. This process has to be fair, open, meaningful and involve the complete integration of the affected tribes in order to insure true tank farm closure.

Response DOE and Ecology acknowledge the preference expressed in the comment and will take this preference and other public comments into consideration when making a final decision on remediating the TWRS waste. Please refer to the response to Comment number 0072.08 for a discussion of the reasons closure alternatives are not appropriate for inclusion in the EIS. Volume One, Section 5.13 of the EIS presents an analysis of the cumulative effects of tank farm remediation and other projects at the Hanford Site. Section 5.13 has been updated to include emerging information concerning the environmental remediation program.

Comment Number 0072.79

CTUIR

Comment P 3-21: PP 4: S 2: Why is it not practical to compare the potential acceptable technologies with the alternatives considering the time and effort used to produce this document? It would seem at the very least to be a reasonable thing to do. If you could not include all of the potential combinations of technologies, how can a reader be sure you have included a full range of applicable technologies?

Response In accordance with the regulations (40 CFR 1500 to 1508) that implement NEPA, the full range of reasonable alternatives were developed and analyzed in the EIS. All other viable technologies and their impacts were also addressed in Volume Two, Appendix B. The purpose of the TWRS EIS was to evaluate reasonable methods or processes (i.e., alternatives) of removing, treating, and disposing of tank waste at the Hanford Site. Including all of the potential combinations of technologies in full alternatives would result in dozens of alternatives to be addressed in the EIS. This would be unmanageable and confusing to the public and the decision makers. Specific removal, treatment, and disposal technologies will be evaluated during the detailed design phase following approval of the Final EIS. Selected technologies will be tested against specific effectiveness and efficiency criteria during the Phase I demonstration (preferred alternative). Please also refer to the response to Comment number 0072.05 and Volume One, Section 3.3 for a detailed explanation of the process used to determine the range of technologies to include in the evaluation.

The Draft EIS addressed the full range of reasonable alternatives. The alternative identified in the comment (i.e., evaluate all potential technologies) is bounded by the alternatives addressed in the Draft EIS, and therefore, DOE and Ecology believe that including the analysis of all the potential combinations of technologies would not provide valuable additional information to the public or decision makers.

Comment Number 0072.177

CTUIR

Comment P B-29: PP2: The in situ alternative may be required by NEPA, but it violates the Tri-Party Agreement. Please insert language regarding this with all in situ alternatives for clarification purposes.

Response The in situ alternatives would not meet the requirements of the Tri-Party Agreement. The Summary, Section S.7 and Volume One, Section 6.2 discuss whether the alternatives meet all applicable laws, regulations, and agreements (including the Tri-Party Agreement). As required by CEQ, the TWRS Draft EIS identifies and analyzes the range of reasonable alternatives for the proposed action. Potential violation of existing laws, regulations, or agreements (any of which may be revised) is not considered basis for eliminating an otherwise reasonable alternative from consideration. Please refer to the response to Comment numbers 0072.80 and 0072.52.

Comment Number 0089.07

Nez Perce Tribe ERWM

Comment Page 3-32, Paragraph 1

The EIS assumed that 99 percent recovery of the tank wastes would be achieved. The remaining 1 percent of tank waste volume left in the tanks will leave a sizable volume of contamination in the tanks to continue to contaminate the vadose zone and groundwater. Future tank closure and soil remediation will not be possible without removal of all tank wastes.

Response The residual waste would likely contain a very low concentration of soluble contaminants because the large volume of liquids used to retrieve the waste would leach the soluble contaminants from the residual waste. The Final EIS presents human health risks based on two scenarios: 1) that the residual waste would contain the average tank contents; and 2) that the residual waste would have been leached to reduce the concentration of soluble contaminants that could be leached into the groundwater. Closure of the tank farms is not within the scope of the EIS. Please refer to the response to Comment number 0072.08 for a discussion of the reasons why closure of the tank farms will be addressed in a future NEPA analysis and 0005.18 for a discussion of the waste retrieval assumption.

Comment Number 0094.01

Moore, Jennifer

Comment I just want to say the thing I find the most disturbing about this EIS, well one of the things I find the most disturbing about this EIS, is the fact that they list not one, not two, but quite a few alternatives which violate the Tri-Party Agreement and other laws and standards. We are dealing with a ... laws which were put so that the public would be protected and that this clean up would keep going at a standard that eventually can ensure that people can live around this area and use the drinking water and basically not live in fear of dying of fatal cancer from being exposed to nuclear waste. The fact the Department of Energy is listing these as viable alternatives, viable options indicates that they do not seem to take the public safety into account very much and somewhat see themselves as above the law which they themselves entered into.

Response The NEPA regulations (40 CFR Parts 1500 to 1508 and 10 CFR 1021) require DOE to evaluate reasonable alternatives even if they do not comply with laws and regulations, so it was necessary to include such alternatives in the EIS. The response to Comment number 0072.80 contains an extensive explanation of NEPA requirements and the criteria used in this EIS to analyze the tank waste alternatives. Please refer to the response to Comment number 0072.05 and Volume One, Section 3.3 for a discussion of how DOE and Ecology identified the alternatives to be analyzed in the EIS. DOE and Ecology's preferred alternative would meet all applicable laws and regulations. Please also refer to the response to Comment numbers 0072.52 and 0072.177.

Comment Number 0097.01

Perry, Henry

Comment Considering that the DOE is representing us, the public, and is playing with more than fire in this situation with the possibility of placing the environment of the entire Pacific Northwest at risk, can there be any question that the EIS, that it prepares, should be prepared on the basis of the worst-case scenario and certainly in accordance with the Tri-Party Agreement previously agreed to.

Response The EIS presents a bounding analysis of the reasonable alternatives. Conservative assumptions and calculation methods are used to provide the public and decision makers with an assessment of the reasonable upper limit of the potential impacts of each alternative if implemented. These assumptions and calculation methods are fully presented in the appendices. The preferred alternative is in full accordance with the Tri-Party Agreement, and in the EIS, the Summary and Volume One, Section 6.2 identify regulatory compliance issues for each alternative. The regulations (40 CFR 1500 to 1508) which implement NEPA and other NEPA implementation guidance discourage the use of "worst case" analyses because these scenarios become unrealistic and blur the differences in impacts between alternatives. The EIS was modified to include an expanded consideration of uncertainties associated with the assumptions and analysis of environmental and human health impacts. The information is presented in Volume Five, Appendix K.

Comment Number 0098.02

Pollet, Gerald

Comment Secondly, in regards to the cost issues, the EIS should clearly compare the cost of the Phased Implementation Tri-Party Agreement path against the risks and costs of the prior Tri-Party Agreement path that were in place for a short period of time before 1994. Under the prior Tri-Party Agreement path, we would retrieve and process approximately twice as much waste by the year 2010 as we will under so-called Phased Implementation. As part of that clear analysis and depiction, the State and the U.S. Department of Energy owe the public and decision makers a clear presentation of the risk each year from delay. In other words, every year you leave more waste in a tank, you have a set of risks. That is why we are hear tonight. You can not deny it. That is ... we all agree that is why we are here. So the question is, does the public deserve to see what is the risk every year from delay. What is the risk from going forward with a path that the General Accounting Office has said may fail. That the State has said is likely to fail. Because of the Department of Energy's contracting decisions which are outside scope of this EIS, but the risks of failure are in the scope of this EIS and need to be disclosed because decision makers for the next decade sitting 3,000 miles away or in the State capital are going to look at this EIS and say, Ah, the risk of another change in the Tri-Party Agreement and another delay in vitrification of 2, 3, 4, 5, 10 years is not so great and we can not let them say that the risks are not so great.

Response The costs of the prior Tri-Party Agreement path are shown in the EIS as the Ex Situ Intermediate Separations alternative costs and the costs of the revised Tri-Party Agreement path are shown as the Phased Implementation alternative costs (without any adjustments for privatization). This information is presented in Volume One, Section 3.4 and Volume Two, Appendix B.

The Phased Implementation alternative would result in less waste being treated during the first 10 years of the project but also would result in all of the waste being treated 4 years earlier than previously required. These two factors would offset each other in terms of releases to the vadose zone before treatment. In any case, the leaks prior to completion are expected to be greatly reduced by the salt-well pumping program, which is currently underway. The Phased Implementation alternative also would decrease the potential for construction of a facility that does not function effectively and thereby reduce the potential for long program delays.

Comment Number 0101.06

Yakama Indian Nation

Comment Invalid Constraints on Scope of EIS Reflecting Lack of Systems Engineering Integration -- The lack of consideration of the impacts associated with the closure of the tank farms following removal of the bulk of the wastes and remediation of the hazardous vadose zone around the tanks is unreasonable, since an integrated systems approach to develop low impact alternatives for tank waste retrieval and tank farm decontamination and decommissioning is warranted to save financial resources and reduce worker exposure. For example, actions required to remediate vadose zones at the tank farms as part of the closure actions may greatly simplify tank waste retrieval actions, reducing costs and expediting retrieval. Cumulative impacts can only be attained when related/integrated actions are evaluated.

Response DOE and Ecology believe that there is sufficient information available to analyze alternatives for remediation of the tank waste even though a number of uncertainties exist for various aspects of the action. These uncertainties are identified in the EIS. DOE is implementing a systems engineering approach to remediation of the tank waste. The integration of tank waste remediation with tank farm closure has been difficult because there is insufficient information available on contamination in the vadose zone and past practice releases. The Notice of Intent to prepare this EIS stated that, "The impacts of closure cannot be meaningfully evaluated at this time. DOE will conduct an appropriate NEPA review, such as an EIS to support closure, in the future" (59 FR 4052).

There is a relationship between closure and tank waste remediation because certain alternatives for tank waste remediation would preclude clean closure of the tank farms. This relationship was discussed in the Draft EIS in Volume One, Section 3.3 on pages 3-18 to 3-20. In addition, a representative closure option, closure as a landfill, was included in all of the remediation alternatives to demonstrate the relationship of closure to remediation and to allow an equitable comparison of the alternatives. This does not mean that closure as a landfill will be selected as the closure alternative, but it provides an assessment of the total potential impacts for the environment. Consistent with NEPA regulations (40 CFR 1500 to 1508), the EIS has been prepared with the most current available information.

The emerging information concerning contamination in the vadose zone was mentioned in the Draft EIS in Volume One, Section 3.4, and the Final EIS has been modified to address the data, as appropriate, in Volume One, Section 4.2 and Volume Five, Appendix K. A systems engineering approach also will be taken to the development of data and engineering when DOE performs a NEPA analysis for closure.

L.3.4 TANK WASTE ALTERNATIVES

L.3.4.1 Preferences for Tank Waste Alternatives

<u>L.3.4.1.1 Specific Preferences</u>

Comment Number 0008.06

Evett, Donald E.

Comment I consider the No Action and Long-Term Management alternatives to be unsuitable for consideration. I believe the impact study reveals significant rationale making this alternative too high of a risk, especially for many years into the future.

Response DOE and Ecology acknowledge the preference expressed in the comment and will take this preference and other public comments into consideration when making a final decision on remediating the TWRS waste. Please also refer to the response to Comment number 0040.01 for a discussion of factors influencing the evaluation of alternatives, and the response to Comment number 0072.80 for issues related to the CEQ, NEPA and the 100-year administrative control period.

Comment Number 0009.07

Broderick, John J.

Comment This alternative (Ex Situ/In Situ Combination) has acceptable risks to workers and offsite public. The other alternatives do not have a significant reduction in fatalities. (About 75 in 10,000 years.) It should be kept in mind that even though statistics indicate a certain level of health effects will be experienced, Hanford will continue to reduce them. The current safety record of Hanford is much better than the national average. We must assume that the good record will continue, and in fact, we must ensure it.

Response DOE and Ecology acknowledge the preference expressed in the comment and will take this preference and other public comments into consideration when making a final decision on remediating the TWRS waste. As noted, the Hanford Site does have a safety record that exceeds the national average, and DOE is committed to continuing improvement of its safety performances. Please refer to Volume One, Section 5.12 and Volume Four, Appendix E, which discuss accident risk during and after remediation. Please also refer to the response to Comment number 0009.06.

Comment Number 0009.08

Broderick, John J.

Comment This alternative (Ex Situ/In Situ Combination) is one of the lowest cost to perform. In addition, it minimizes repository costs. We do not know what the repository costs will be, but it is unlikely that they will be lower than the current estimates.

Response DOE and Ecology acknowledge the preference expressed in the comment and will take this preference and other public comments into consideration when making a final decision on remediating the TWRS waste. A discussion of factors influencing the evaluation of alternatives is provided in the Summary (Section S.6), a comparison among the alternatives is provided in the Summary (Section S.7), and a summary of the environmental impacts is presented in Volume One, Section 5.14.

A reevaluation of repository costs, which accounted for the use of larger canisters in the geologic repository, led to a reduction in repository costs for some alternatives. These revised costs have been presented in the Final EIS in Volume One, Section 3.4 and Volume Two, Appendix B. The response to Comment numbers 0081.02, 0004.01, and 0008.01 extensively discuss the issues related to repository costs.

Comment Number 0009.09

Broderick, John J.

Comment This alternative (Ex Situ/In Situ Combination) will have the facilities constructed by 2007. This is faster than most of the alternatives. Speed is very important because it seems that Hanford, as time goes on loses its concentration and wants to do something else. The number of canceled projects is very large, and very expensive.

Response DOE and Ecology acknowledge the preference expressed in the comment and will take this preference and other public comments into consideration when making a final decision on remediating the TWRS waste.

DOE and Ecology acknowledge the risks associated with projects that take a long time to complete. However, speed of project completion is but one of many factors that influence the evaluation of alternatives. Other factors analyzed include short- and long-term risk to human health and the environment, technical uncertainty, cost, and regulatory compliance. Please refer to the response to Comment numbers 0009.08 and 0009.10.

Comment Number 0009.11

Broderick, John J.

Comment This alternative (Ex Situ/In Situ Combination) does not meet all of the regulations; however, they can be negotiated to be modified to assure that the public is adequately protected. The Tri-Party Agreement is a good place to document the negotiations.

Response DOE and Ecology acknowledge the preference expressed in the comment and will take this preference and other public comments into consideration when making a final decision on remediating the TWRS waste. The ability of the alternatives analyzed in the EIS to comply with Federal and State regulations is presented in the Summary (Section S.7) and discussed in detail in Volume One, Section 5.7.

Comment Number 0009.16

Broderick, John J.

Comment The Preferred Alternative is not acceptable because the cost (for the Preferred Alternative) is not the lowest that provides adequate protection of the public.

Response DOE and Ecology acknowledge the objection to selection of the Phased Implementation alternative as the preferred alternative, and this comment and other public comments will be taken into consideration when making a final decision on remediating TWRS waste. Please refer to the response to Comment number 0009.15. As discussed in the Summary (Section S.6), there are a number of factors that influence the evaluation of the alternatives. Cost was one factor analyzed for each alternative. The results of the impacts analysis are presented in the EIS in an objective, nonvalue-laden (e.g., less or more cost is preferable) manner for careful consideration by the public and decision makers. Cost comparison of the alternatives was never conducted in the absence of all other factors, which included risk to human health and the environment, long-term land use restrictions, and regulatory compliance. Furthermore, for the final EIS cost impacts associated with HLW storage at the proposed geologic repository have been presented separate from costs associated with the waste management, retrieval, treatment, and disposal or disposal onsite. For example in comparing the Ex Situ/In Situ Combination 1 alternative to the Phased Implementation alternative, the cost of long-term land use restrictions and risk to human health and the environment, as well as cost, monetary or other, of not complying with current regulatory requirements were analyzed equally. Please refer to the response to Comment number 0081.02 for discussions of cost issues related to the alternatives.

Miscellaneous Preferences

Comment Number 0001.01

Bell, Robert C.

Comment There currently exists containment technology that could completely seal off the leaking nuclear contaminants from migrating through the earth and contaminating the groundwater. However, it appears that no monies have been budgeted for the containment of the leaking nuclear waste. By containing the leaking storage tanks the public along with all life would be protected from the most toxic and deadly nuclear waste. I urge you to actively support the request to the United States Congress for funds to pay for the containment of the leaking tanks at Hanford.

Response Subsurface barriers are addressed in the EIS as a containment technology that could be applied to control tank leakage. The function of the subsurface barriers would be to prevent leakage of tank waste from migrating beyond the barrier into the vadose zone, which would help minimize the volume of contaminated soil. The possible use of subsurface barriers was derived from concerns about using hydraulic sluicing for retrieval, and because some of the SSTs either are confirmed or assumed leakers. Also, a study titled Feasibility Study of Tank Leakage Mitigation Using Subsurface Barrier (Treat et al. 1995) was completed in support of a Tri-Party Agreement milestone and was one of the references used during preparation of this EIS. The feasibility study assessed the application of existing

subsurface barrier technologies and the potential of existing technologies to meet functional requirements for SST waste storage and retrieval activities. Information on subsurface barriers is included in Volume Two, Section B.9.

In addition, the current TWRS program involves a wide variety of ongoing activities that include monitoring the integrity of tanks and characterizing the vadose zone around the tank farms to detect leaks. DOE also conducts numerous activities to provide continued safe storage of the tank waste, such as the saltwell pumping program, which involves removing retrievable liquids from SSTs to minimize potential future leaks. These ongoing programs are described in Volume One, Section 3.2.

This EIS addresses the full range of reasonable alternatives. This includes 10 tank waste alternatives ranging from no action to extensive retrieval. Risk to human health and the environment was among the factors considered by DOE and Ecology in identifying the preferred alternative, Phased Implementation (a discussion of factors that influence the evaluation of alternatives is presented in the Summary, Section S.6). Volume One, Section 5.13 (Cumulative Impacts) addresses actions at other DOE sites, programmatic actions, and actions at the Hanford Site that could impact the TWRS actions, including the Hanford Remedial Action Program. The proposed TWRS activities would be carried out against the baseline of overall Hanford Site operations. Volume One, Section 5.11 and Volume Three, Appendix D detail the anticipated risk for each alternative.

DOE and Ecology acknowledge the recommendation expressed in the comment regarding funding. However, Congressional funding issues are not included in the scope of this EIS.

Comment Number 0040.01

Rogers, Gordon J.

Comment The In Situ Fill and Cap alternative is clearly the best choice. The cost is low enough to have some real chance of being funded by Congress. It reaches a reasonable stage of completion in the shortest time. The short-term impacts are trivial. The long-term impacts appear likely to be small and acceptable providing that onsite use of groundwater is prohibited; and further than onsite farming and irrigation is prohibited.

Response DOE and Ecology acknowledge the preference expressed in the comment and will take this preference and other public comments into consideration when making a final decision on remediating the TWRS waste. Short- and long-term environmental impacts, uncertainties, and regulatory compliance are among the factors influencing the evaluation of alternatives. A discussion of these and other factors influencing the evaluation of alternatives is provided in the Summary, Section S.6, a comparison among the alternatives is presented in the Summary, Section S.7, and a summary of environmental impacts is provided in Volume One, Section 5.14.

NEPA requires that all reasonable alternatives be evaluated, regardless of cost, although Congressional funding issues associated with implementation of the alternatives were not included in the scope of the EIS. Please refer to the discussion contained in the response to cost concerns related to a comparison of the alternatives contained in Comment number 0081.02.

Comment Number 0072.11

CTUIR

Comment Of the alternatives presented, the CTUIR SSRP technical staff prefers Ex Situ with Extensive Separations because the cost is comparable, the volume of waste is comparable, the technical uncertainty is no higher than the other ex situ alternatives, and the activity of the LAW would be substantially lower than with less extensive separations. The phased approach will not be practical since substantially more land is required for two sets of vitrification facilities rather than the one set required for the non-phased options.

Response DOE and Ecology acknowledge the preference expressed in the comment and will take this preference and other public comments into consideration when making a final decision on remediating the TWRS waste. Multiple factors, including land-use commitments, influence the evaluation of alternatives. Among the factors are short- and long-term environmental impacts, regulatory compliance and uncertainties. These factors are addressed in the EIS in the Summary, Section S.6. In the Summary, Section S.7 contains a comparison of the alternatives based on various evaluation factors and Volume One, Section 5.14 provides a summary comparison of all of the environmental impacts addressed in the various sections of Volume One, Section 5.0 and the supporting appendices. The response to Comment number 0081.02 contains a discussion of the comparison impact of separating repository costs from retrieval and treatment costs of the ex situ alternatives.

Land use commitment impacts were analyzed in detail in Volume One, Section 5.7. Based on that analysis, Volume

One, Section 5.19 identifies potential land use restrictions as a potential environmental justice concern for affected Tribal Nations. Volume One, Section 5.20 identifies potential mitigation measures that could be implemented to address the land use impacts identified in Section 5.19. For the Final EIS, these sections of the Draft EIS were revised to reflect technical information unavailable at the time the Draft EIS was published.

Comment Number 0085.02

Klein, Robin

Comment While it is true that a clearly proven, good solution does not exist, it is also true that the liquid wastes must not remain in these tanks. The leaking tanks are the greatest source of waste contaminations to the soils. Contaminated waste originating from the tanks are moving toward groundwater. Groundwater contaminated with Hanford pollutants already in the soils is now in communication with the Columbia River. Cleaning up waste once in the soils will take heroic efforts. Once they get into the river, the long lived contaminants are practically irretrievable. The single most affective measure we can take to protect the river in the long run is to stop the driving force that enables rapid migration of the wastes offsite, get the waste out of the leaking tanks soon. So it is important to have an aggressive plan in place.

Response DOE and Ecology acknowledge the preference expressed in the comment and will take this preference and other public comments into consideration when making a final decision on remediating the TWRS waste. DOE and Ecology are committed to protecting the Columbia River. Please refer to the response to Comment number 0040.01 for a discussion of factors influencing the evaluation of alternatives.

Comment Number 0088.03

Porter, Lynn

Comment There's an article in the Oregonian Sunday March 17th, that raised a whole lot of questions. This was a large article beginning on the front page quoting a panel of scientists from the National Research Council, whoever that is, I probably should know, but I don't. And they're saying just leave the stuff in the tanks. They quote some DOE engineers saying yes we can do it. And one of the points that puzzled me was they're saying in this article, the National Research Council says that before you can sluice out these tanks you have to seal the ground underneath them. I didn't find anything about that in the summary of the Draft EIS, except for the ISV option. So I don't know where this comes from, but their point seems to be that if you're going to have to seal the ground anyway, you might as well leave the stuff in the tanks. That's something I would have like to of heard discussed.

I think the problem is that this kind of thing keeps coming up. And so of course we wonder where's it coming from. There seems to be a lot of energy behind this idea we'll just leave the stuff in the tanks and put it cap on it and walk away. I'm glad to hear that isn't the feeling at the top. But since it keeps coming up in such volume, we wonder what's going on, like is this a trial balloon. If it is, I'd like to shoot it down. I just think leaving the stuff in the tanks is a completely unacceptable alternative. And I wish someone would take this idea out and bury it and drive a stake through it's heart.

Response DOE and Ecology acknowledge the preference expressed in the comment and will take this preference and other public comments into consideration when making a final decision on remediating the TWRS waste. The National Research Council, in the cited article, advocated an alternative that evaluated the impact of not removing waste from selected tanks. This alternative, which corresponds to the Ex Situ/In Situ Combination 1 and Ex Situ/In Situ Combination 2 alternatives evaluated in the EIS, is not the preferred approach endorsed by DOE and Ecology. Please refer to the response to Comment number 0040.01 for a discussion of factors influencing the evaluation of alternatives and Comment number 0001.01, which discusses subsurface barriers as this issue relates to leak containment.

Specific Preference for Ex Situ/In Situ Combination Alternative

Comment Number 0009.05

Broderick, John J.

Comment The above reasoning has lead me to recommend you select the following remediation alternative: Ex Situ/In Situ Combination. I believe the Preferred Alternative is doomed to be not completed because it is trying to avoid leaving waste in place, will take too long to construct, and will cost too much. In addition, there is a possibility that the whole issue will again be revisited at the beginning of the second phase. This will be another opportunity to change the remediation approach.

Response DOE and Ecology acknowledge the preference expressed in the comment and will take this preference and other public comments into consideration when making a final decision on remediating the TWRS waste. Please refer to the response to Comment number 0009.06 for a description of revisions to the alternatives in the Final EIS, 0009.08 for a description of the factors considered when evaluating alternatives, and 0009.09 for a description of the time required to implement alternatives.

Comment Number 0009.06

Broderick, John J.

Comment This alternative (Ex Situ/In Situ Combination) selects the actions based on long term health effects, rather than a "one size fits all" approach.

Response The ex situ/in situ combination alternatives are based on reduction of human health risk and different tanks having much different contents, therefore representing differing potential long-term impacts to human health. For the Final EIS, two ex situ/in situ combination alternatives are analyzed in detail. Volume One, Section 3.4 and Volume Two, Appendix B provide a description of the two alternatives and the potential impacts associated with each alternative are analyzed in Volume One, Section 5.0 and associated appendices.

Comment Number 0009.10

Broderick, John J.

Comment This alternative (Ex Situ/In Situ Combination) will deal with more waste faster than other, more extensive alternatives. Thus there will be less effort expended in just managing the waste.

Response DOE and Ecology acknowledge the risks associated with projects that take a long time to complete. However, speed of completion of the project was one of many factors that influence the evaluation of alternatives (please refer to the response to Comment number 0009.08). Duration of construction and remediation is directly proportional to the nature and volume of tank waste, as well as the complexity of the tank farms as a whole (i.e., vadose zone contamination, groundwater migration, and closure). The preferred alternative, using a phased approach, would allow evaluation and optimization of the technologies used to treat the waste form and nature to be retrieved, which would enable the Agencies to apply "best fit" for the waste type. A summary of the environmental impacts of all alternatives analyzed in the EIS is presented in Volume One, Section 5.14 and a comparison of the alternatives is presented in the Summary (Section S.7).

Comment Number 0009.12

Broderick, John J.

Comment This alternative (Ex Situ/In Situ Combination) will provide means so the waste will not migrate from its disposal location. Still, there will be waste present, so there must be a continuing program to restrict farming, groundwater use, and intrusion. This program will be much less expensive and less complicated than removing all waste from Hanford.

Response DOE and Ecology acknowledge the preference expressed in the comment and will take this preference and other public comments into consideration when making a final decision on remediating the TWRS waste. For purposes of analysis in the EIS, institutional controls for this and other alternatives would end 100 years following the end of remediation. Thus, the long-term impacts assume unrestricted use of the Site for farming and potential use of groundwater as well as intrusion into the waste disposal onsite. Therefore, while the cost, technical complexity, and short-term impacts of the combination alternatives are less than that of the ex situ alternative; long-term impacts tend to be higher. For a comparison of the alternatives, please refer to the Summary, Section in 5.7.

Comment Number 0009.15

Broderick, John J.

Comment The Preferred Alternative is not acceptable because the extra effort (for the Preferred Alternative) does not significantly reduce the fatalities expected, even though all the waste is removed.

Response DOE and Ecology acknowledge the preference expressed in the comment, but have identified the Phased Implementation alternative as the preferred alternative for the reasons described in the Summary (Section S.7). As discussed in Section S.6, there are a number of factors that influence the evaluation of the alternatives including short-term and long-term impacts, uncertainties, and compliance with laws and regulations. Please also refer to the response to Comment number 0098.06 for more information about risk calculation. Reduction in fatalities is one method of comparing alternatives; however, other issues such as regulatory compliance, long-term reduction in potential risks to human health and the environment, and implementability in light of technical uncertainty must also be considered.

Comment Number 0009.17

Broderick, John J.

Comment The Preferred Alternative is not acceptable because there will be significant repository costs (for the Preferred Alternative). The costs are uncertain now because we do not have a repository.

Response DOE and Ecology acknowledge the preference expressed in the comment and will take this preference and other public comments into consideration when making a final decision on remediating the TWRS waste. The repository cost for each alternative was calculated to provide the public and decision makers with information associated with the total potential costs of the various alternatives. Based on new information made available since the publication of the Draft EIS, repository costs have been substantially revised for the Final EIS (Volume One, Section 3.4 and Volume Two, Appendix B). A discussion of the methodology used to calculate repository costs, the cost associated with each alternative, cost formulas, and canister size issues, is contained in the response to Comment numbers 0081.02, 0004.01, and 0008.01.

Comment Number 0009.18

Broderick, John J.

Comment The preferred alternative is not acceptable because the construction of facilities will not be completed until 2012 (for the preferred alternative). This is way too long, our experience is that long duration projects often do not reach the operational phase.

Response DOE and Ecology acknowledge the preference expressed in the comment and will take this preference and other public comments into consideration when making a final decision on remediating the TWRS waste. Phase 1 of this alternative (construction and operations) would be completed in 2007. Phase 2 construction would be completed in approximately 2011. DOE and Ecology acknowledge the risks associated with projects that take a long time to complete. However, speed of completion of the project is but one of many factors that influence the evaluation of alternatives. Please refer to response to Comment numbers 0009.09, 0009.10, and 0098.02, which discusses issues related to construction starts and duration and the impact of the phased approach on the volume of waste treated.

Comment Number 0009.19

Broderick, John J.

Comment The Preferred Alternative is not acceptable because the phased approach is not needed. We can build the facilities with existing technology. As our knowledge and experience increase over the next 45 years, we can modify the facilities. We will need to do that anyway to keep up with technology and safety requirements.

Response DOE and Ecology acknowledge the preference expressed in the comment and will take this preference and other public comments into consideration when making a final decision on remediating the TWRS waste. The preferred alternative, Phased Implementation, represents near-term use of currently available technologies to the extent possible. Phase 1, also known as the demonstration period, will assess the capability and effectiveness of existing technologies to retrieve and treat the waste and provide DOE with information on retrieval efficiencies, blending practices, separation efficiencies, vitrification techniques, and costs prior to constructing and operating full-scale facilities. This will result in more efficiently designed and operated facilities for Phase 2. The implementation schedule for the preferred alternative is consistent with Tri-Party Agreement milestones, as well as concurrent with other programmatic and systems activities currently conducted at the Site. Because the phased approach is designed to implement "learn as you go" improvements, system optimization and cost savings are expected. This approach and resulting benefits may be less likely with a fixed, less flexible technology or implementation of full-scale facilities without a demonstration phase. For a discussion of the phased approach to alternative implementation, see Volume One, Section 3.4 and Volume Two, Appendix B. Please refer to the response to Comment number 0098.02 for a discussion of schedule and treatment volume estimates associated with the preferred alternative.

Comment Number 0029.01

Bartholomew, Dale C.

Comment I believe that the Ex Situ/In Situ Combination alternative offers the best balance between risk and benefit of the proposed alternatives and should be selected as the preferred alternative for the following reasons:

It offers the highest real value. It provides a level of safety to the public commensurate with other sub-surface contamination immediately adjacent to some of the tanks, adjacent to the 242-S evaporator, and sites such as cribs throughout the 200 Areas as well as other contaminated areas adjacent to the 200 Areas such as BC Crib. If my understanding is correct, no further action is planned on these other sites. Therefore, totally uncontrolled access by the public would be unacceptable, and I recommend that a waiver be obtained for relief for tank wastes from the regulations. This may be politically incorrect, but makes the most sense in the context of a balanced total system.

Retrieval of wastes from all SSTs, DSTs, and MUSTs is a huge waste of money if the soil contamination sites outside the tanks are not also ameliorated.

I also believe retrieval of wastes from all tanks creates a higher-than-projected exposure of working personnel to both occupational and radiological accidents and injuries. I have no data to support this. However, my experience suggests that the input data for the calculations may not be realistic.

The Summary Table indicates that the Ex Situ/In Situ Combination alternative and the preferred alternative are both rated "moderate" with respect to Technical Uncertainty. I believe the degree of technical uncertainty associated with the Ex Situ/In Situ Combination is less than the preferred alternative because only one-half of the waste volumes would be vitrified and sent to the repository with the Ex Situ/In Situ Combination alternative, (50 percent of the tanks would be filled and capped). It should have received a lower Technical Uncertainty rating because of scaled-down throughput requirements.

I suspect when wastes from all of the tanks are retrieved, there will be several SSTs thought to be non-leakers that will be found to be leakers. That will only add to existing soil contamination during sluicing.

I noticed where the U-238, Tc-99, C-14, and I-129 isotopes were to be retrieved. I fully support this action. I may have read the document too quickly, but I did not notice any reference to TRU wastes. Obviously, these must also be removed and vitrified.

Response DOE and Ecology acknowledge the preference expressed in the comment and will take this preference and other public comments into consideration when making a final decision on remediating the TWRS waste.

The following responses are in the same order as the comments.

Short-term and long-term impacts to human health and the environment, managing the uncertainties associated with the waste characteristics and treatment technologies, cost, and compliance with laws, regulations, and policies are among the factors considered when evaluating the alternatives (please refer to the response to Comment number 0009.08). No decision has been made regarding remediation of subsurface contamination adjacent to the tanks or in the other areas referred to in the comment. Contamination from past tank leaks is beyond the scope of this EIS (see Volume One, Section 3.3 and the response to Comment number 0072.08). Other contamination of soils in the 200 Areas is the subject of the Hanford Remedial Action EIS and subsequent Comprehensive Environmental Response, Comprehensive Environmental Response Compensation and Liability Act (CERCLA) decisions. The TWRS EIS presents the cumulative impacts of the tank waste alternatives and the 200 Areas contamination in Volume One, Section 5.3).

The retrieval of wastes from the SSTs, DSTs, and MUSTs and their subsequent remediation is considered in this EIS. Tank waste retrieval and treatment is the first step in remediation of the tank farms. The remediation of soil contaminated sites outside the tanks will be considered in other environmental documentation, such as the Hanford Remedial Action EIS. The EIS analyzes a range of alternatives from no waste retrieval to extensive waste retrieval. Each of the alternatives presents differing trade-offs among short-term and long-term environmental impacts, technical uncertainty, and regulating compliance. Additionally, alternatives that involve no retrieval or partial retrieval, such as the ex situ/in situ combination alternatives would influence the closure actions that could be implemented, as discussed in Volume One, Section 3.3. Implementation of these alternatives would limit or potentially increase the cost and complexity of the future closure actions such as remediation of contaminated soils. Extensive retrieval alternatives would provide the least complications and cost impacts on future closure actions.

The risks to the workers during construction and operation of the retrieval and transfer facilities for the ex situ alternatives have been analyzed for all the alternatives. The results of this analysis are given in Volume Four, Appendix E and in Volume One, Section 5.12. In general, risks to the workers are less when less retrieval and transfer are conducted. Regardless of the alternative selected, DOE would complete a detailed safety analysis of the alternative to determine additional safety measures for implementation. Please refer to the response to Comment number 0098.06 for risk calculation information.

The technical uncertainty of an alternative is a compilation of numerous factors, such as similarity to other like operations, the history of demonstrated performance of the technology, the ability to construct and operate the alternative given the conditions at the Site, and others. However, if two technologies are operating at roughly the same scale and production rate, the technical uncertainty is not a direct function of the throughput requirement. The ability to design, construct, and operate the Phased Implementation alternative and the ex situ/in situ combination alternatives are approximately the same. Both alternatives have approximately the same degree of process development, consequently, the two processes will be rated about equal in their technical uncertainty.

To account for leakage from the SSTs during retrieval, the EIS assumes an average of 4,000 gallons of leakage from each tank (see Volume One, Section 5.2 and Volume Four, Appendix F). It is not expected that all SSTs will leak this amount. Some SSTs will not leak during retrieval, and as the comment suggests, some SSTs will develop unexpected leaks. It has been assumed in the EIS that the total leakage divided by the number of tanks will be bounded by the 4,000-gallon figure. For tanks that are known leakers or that develop leaks during retrieval, the EIS presents technology options to sluicing, such as robotic arm-based retrieval, that would involve substantially lower volumes of liquids (see Volume One, Section 3.4 and Volume Two, Appendix B).

The purpose is to retrieve the radionuclides that are the chief contributors to long-term risk (i.e., uranium-238, technetium-99, carbon-14, and iodine-129). Neptunium-237, a TRU isotope, is also a contributor to long-term risk, and this alternative shows a calculated retrieval of approximately 93 percent for this isotope. There is a large calculated proportion of other TRU elements that would be retrieved, but do not move quickly enough in the vadose zone and groundwater to contribute to risk within 10,000 years.

Specific Preference for the Phased Implementation Alternative

Comment Number 0012.01

ODOE

Comment Governor Kitzhaber and Oregon strongly support the preferred alternative in the environmental impact statement (EIS). This alternative calls for a retrieval of all of the tank wastes technically possible (estimated at 99 percent of the wastes) and vitrifying the wastes. While the vitrified wastes will still be radioactive, they will be safer to store and not susceptible to leakage pending ultimate disposal.

Although we support the preferred alternative, it will not resolve all the issues related to the high-level wastes at Hanford. We believe there will continue to be the need for ongoing monitoring, characterization, and pumping and treating of groundwater contamination caused by waste which has leaked and migrated from the tanks.

Response DOE and Ecology acknowledge the preference of the State of Oregon for the preferred alternative, and will take this preference and other public comments into consideration when selecting the final action for TWRS waste. The issues identified were among the factors considered by DOE and Ecology in identifying the preferred alternative.

The Hanford Site will require ongoing monitoring and characterization relative to past tank leaks and the migration resulting from those leaks into the surrounding environment. The characterization and monitoring programs are discussed in the response to Comment numbers 0072.61, 0072.63, 0072.67, and 0072.70. Each of the alternatives includes continuation of existing programs to characterize vadose zone and groundwater contamination and long-term monitoring programs that extend beyond the completion of the tank waste action (Volume One, Section 3.4 and Volume Two, Appendix B). As more information becomes available regarding the environmental consequences of past leaks and the nature of residual waste remaining in the tanks following retrieval, DOE will be able to address actions associated with tank farm closure, including the potential for pumping and treating groundwater contamination beneath the 200 Areas (see Volume One, Section 3.3 for a discussion of closure). It is because of the lack of adequate data regarding these issues that the closure of the tank farms is not included in the scope of this EIS. Please refer to the response to Comment number 0072.08.

Comment Number 0012.03

ODOE

Comment Leaving wastes in the tanks poses huge risks. The tanks are corroding and failing. As they fail, the radioactive waste is released to the soil and ultimately to the groundwater and to the Columbia River. Vitrifying the tank waste makes it far more stable and greatly reduces the threat to the public and the environment. While the cost of the preferred alternative is substantial, it is the only alternative which satisfactorily deals with the dangers presented by these wastes as quickly as practical. The phased approach allows USDOE to get on with cleanup while allowing for possible development of better approaches which remove all tank wastes.

Response DOE and Ecology acknowledge the preference expressed in the comment and will take this preference and other public comments into consideration when making a final decision on remediating the TWRS waste. The issues identified were among the factors considered by DOE and Ecology in identifying the preferred alternative, Phased Implementation. Please refer to the response to Comment number 0009.19 for reasons the Phased Implementation was identified as the preferred alternative.

Comment Number 0012.07

ODOE

Comment The preferred alternative relies on proven technology and a phased approach. This allows a "learn as you go approach" which should identify problems earlier and at a smaller economic and environmental cost.

Response DOE and Ecology acknowledge the preference expressed in the comment and will take this preference and other public comments into consideration when making a final decision on remediating the TWRS waste. The issues identified were among the factors that influence the evaluation of alternatives. Please refer to the Summary, Section S.6 and S.7 and the response to Comment numbers 0009.08 and 0009.19.

Comment Number 0012.09

ODOE

Comment The current risk modeling and analysis are too simplistic to allow detailed decisions which call for leaving part of the wastes in place and still protect human health and the environment. We believe the risk assessment in this EIS is sufficient to support the proposed alternative and to conclude that the risks are too large to allow any of the tank waste to remain in the tanks at the end of cleanup.

Response The risk modeling and assessment performed for this EIS used the best available data, state-of-the-art models, and industry standard approaches and techniques and is both comprehensive and detailed. The data generated by the modeling and assessment provided for a balanced and equitable comparison among the alternatives and as such, provided results that were useful in comparing the potential short-term and long-term human health and environmental impacts. To the extent that the risk assessment provided sufficient data to evaluate the preferred alternative, it also provided equally valid data to support the evaluation of all alternatives, including alternatives involving leaving some or all of the waste in place. For the Final EIS, an appendix (Volume Five, Appendix K) was added to the EIS to provide a basis for understanding uncertainties associated with the risk assessment, as well as other areas of uncertainties.

Comment Number 0022.03

Sims, Lynn

Comment We know millions of gallons of waste have already leaked from the tanks and migrated towards groundwater. This relentless assault upon the environment will not cease without intervention. We are not certain of the environmental and human health damage which has and will result from leaking tanks, but forecasts are ominous. The only responsible alternative is the preferred alternative which removes as much waste as possible and isolates them from the environment by vitrification.

Response DOE and Ecology acknowledge the preference expressed in this comment and will take into consideration this preference and other public comments when selecting the final action for TWRS waste. DOE has implemented a program to remove as much of the liquids as practicable from the SSTs to reduce the likelihood of future leaks. A discussion of this program is provided in Volume One, Section 3.4 and Volume Two, Appendix B. An analysis of potential cumulative impacts, including past leaks is presented in Volume One, Section 5.13 and new information regarding the extent of migration of past leaks to the vadose zone and groundwater has been included in Volume Five, Appendix K. The ongoing characterization and monitoring program is discussed in the response to Comment numbers 0072.61, 0072.63, 0072.67, and 0072.70.

Comment Number 0032.04

Heacock, Harold

Comment We support the Department's preferred alternative of phased implementation of an ex situ intermediate separations process, which provides for the greatest protection of the environment, including protection of the groundwater consistent with a reasonable projected cost, the disposal of the vitrified high-level waste at a national waste repository, and an acceptable degree of risk.

Response DOE and Ecology acknowledge the preference expressed in the comment and will take this preference and

other public comments into consideration when making a final decision on remediating the TWRS waste. Pleaser refer to the response to Comment number 0009.19 for a discussion of the reasons Phased Implementation is the preferred alternative.

Comment Number 0035.08

Martin, Todd

Comment I would like to address what I think is good in the EIS. We support the pretreatment selection in the preferred alternative.

Intermediate separations is appropriate. HEAL would vigorously oppose any movement towards extensive separations pretreatment process.

The stakeholder community in the Northwest has made it very clear that intermediate separations is responsive to our values. It is available relatively, and it will reduce the waste volume by a satisfactory amount.

Secondly I support the assumption that 99 percent of the waste will be retrieved. The risks in the EIS show very clearly that the only responsible alternative is to retrieve all of the waste.

Response DOE and Ecology acknowledge the preference expressed in the comment and will take this preference and other public comments into consideration when making a final decision on remediating the TWRS waste. Please refer to the response to Comment number 0005.38 for a discussion of issues related to pretreatment. The response to Comment number 0012.19 contains a detailed discussion of the extent to which the public has made a positive impact on this document.

Comment Number 0036.10

HEAL

Comment HEAL supports the full retrieval of Hanford's tank wastes. The preferred alternative's retrieval scenario is responsive to the stakeholder values. It has always been assumed that Hanford's tank wastes post a great risk to future generations. This EIS confirms the assumption. The EIS shows that future risk is directly correlated to the amount of waste left behind. The impact of leaving only a small portion of contamination behind is evidenced by the difference in long-term risk for the preferred alternative where 1 percent of the waste is left and the Ex Situ/In Situ alternative where 10 percent of the waste is left behind. By leaving 9 percent more waste behind, the risk for residential farmer at 5,000 years would increase by a factor of 10. These high risks clearly show that the only responsible solution is to retrieve all of the waste.

Response DOE and Ecology acknowledge the preference expressed in the comment and will take this preference and other public comments into consideration when making a final decision on remediating the TWRS waste. Impact to the public welfare, including residential farmers, was a factor analyzed for all alternatives. Please refer to the response to Comment number 0009.05. The environmental impacts of all the alternatives analyzed in the EIS are summarized in Volume One, Section 5.14. Potential long-term health effects are summarized for each alternative in the Summary, Section S.7.

Comment Number 0038.03

Reeves, Merilyn

Comment Now, the board supports the full retrieval from Hanford tank waste. The preferred alternative retrieval scenario is responsive to the board's value.

Response DOE and Ecology acknowledge the preference expressed in the comment and will take this preference and other public comments into consideration when making a final decision on remediating the TWRS waste. Please refer to the response to Comment number 0009.19 for a discussion of the reasons the Phased Implementation alternative is the preferred alternative.

Comment Number 0038.05

Reeves, Merilyn

Comment The Board supports the preferred alternative's pretreatment process. And again, we go back to the Tank Waste Task Force, which stated the high cost and uncertainty of high tech pretreatment and R and D threatens funding for higher performance low level waste form vitrification and cleanup.

Use the more practical, timely, available technology while leaving room for future innovations. Keep a folio of technology options and make strategic investments over time to support the limited number of promising options. Give up further research on unlikely options. Again a statement from 1993.

The intermediate separations case is responsive to this value although the difficult challenge of technetium removal in the Phased Implementation alternative is a concern to the Board.

And the Board would strongly oppose any movement towards extensive separations pretreatment technology.

Response DOE and Ecology acknowledge the preference expressed in the comment and will take this preference and other public comments into consideration when making a final decision on remediating the TWRS waste. Please refer to the response to Comment number 0072.05 for a description of how the alternatives analyzed in the EIS were identified and methods for analyzing technology options in the EIS.

Implementing Phase 1 of the preferred alternative would allow evaluation of existing technologies while moving forward on retrieval and treatment goals. As the demonstration phase progresses, the efficiencies and effectiveness of the retrieval and treatment technologies, including technetium separation, can be evaluated and optimized. Technetium removal could be implemented during Phase 1 using established separations technology or emerging technologies that show promise in keeping with recommendations of the board. One way of removing technetium-99 from alkaline waste solutions is to selectively sorb the isotope, as TcO_4, using a strong-base organic ion-exchanger (WHC 1995a).

Comment Number 0042.01

EPA

Comment The EIS addresses the treatment, storage, and disposal of Hanford Tank Waste to meet the requirements of the Hanford Federal Facility Agreement and Consent Order and the Resource Conservation and Recovery Act as amended by the Hazardous and Solid Waste Amendments of 1984. As a signatory to the Agreement and Consent Order, EPA has endorsed the approach identified in the Draft EIS as the preferred alternative.

Response DOE and Ecology acknowledge the preference expressed in the comment and will take this preference and other public comments into consideration when making a final decision on remediating the TWRS waste. Please refer to the response to Comment numbers 0072.05 and 0005.07.

Comment Number 0043.02

Hanford Communities

Comment In its selection of an alternative for the cleanup of tank wastes, we believe that the Department of Energy must comply with State and Federal laws and must also comply with its commitments under the Tri-Party Agreement. We believe that the Department should proceed with an ex situ process of extensive waste retrieval with phased implementation. This process appears to have the strongest backing of people in this area and provides the best long-term environmental solution.

Response DOE and Ecology acknowledge the preference expressed in the comment and will take this preference and other public comments into consideration when making a final decision on remediating the TWRS waste. DOE and Ecology intend to comply with all Federal, State, and local regulations and ordinances applicable to tank waste remediation. Please refer to the response to Comment number 0040.01 for a discussion of factors influencing the evaluation of alternatives.

Comment Number 0076.01

Blazek, Mary Lou

Comment I had passed out a comment, or a formal comment that I would like to have read into the record. I won't do that now, it would be lengthy. I just like want to say on the record that Governor Kitzhaber and the Oregon Department of Energy strongly support the proposed alternative in this Environmental Impact Statement. The retrieval for all the tank waste that are technically possible, up to 99 percent we think is critical that occur. The need for this undertaking is compelling in our minds. The potential impact to the Columbia River cannot be impacted in this way.

Response DOE and Ecology acknowledge the preference expressed in the comment and will take this preference and other public comments into consideration when making a final decision on remediating the TWRS waste. DOE and Ecology remain committed to protecting the Columbia River and the analysis of potential impacts of TWRS alternatives includes impacts to the River as presented in Volume One, Section 5.2 and Volume Four, Appendix F. Please refer to the response to Comment number 0040.01 for a discussion of factors influencing the evaluation of alternatives.

Comment Number 0076.02

Blazek, Mary Lou

Comment The other alternatives under consideration leave most, or all of the waste in the tanks, with the exception of the in situ vitrification, which is an immature and unproven technology. Other alternatives do little to remove the hazards posed by the waste. The major criteria that must be applied to any decision is the protection of public health and safety and the environment. This criteria eliminates all of the alternatives, which leave all or part of the waste in the tanks, except in situ vitrification. The EIS claims a lower risk for in situ vitrification, although it's an immature and unproven technology. Because the in situ vitrification technology is uncertain, we oppose all of the alternatives, which leaves the waste in Hanford tanks.

Response DOE and Ecology acknowledge the preference expressed in the comment and will take this preference and other public comments into consideration when making a final decision on remediating the TWRS waste. Please refer to the response to Comment number 0040.01 for a discussion of factors influencing the evaluation of alternatives and 0005.18, which discusses tank waste residuals.

Comment Number 0077.03

ODOE

Comment Sacrificing Hanford in this way does not adequately reduce the harm and risks to the environment or to future generations. For these alternatives, the risk analyses in the EIS show massive plumes of radioactive material slowly moving across the Hanford site and into the Columbia River for hundreds to thousands of years.

Cost should not be the sole or even predominant criteria used to select among the alternatives. The first criteria that must be applied is protection of public health and safety and the environment. This criteria eliminates all of the alternatives which leave all or part of the waste in the tanks, except in situ vitrification. The EIS claims a lower risk for in situ vitrification, although it is an immature and unproven technology for tank waste. Because in situ vitrification technology is uncertain, the potential for failure is unacceptably high. We strongly oppose all of the alternatives which leave the waste in Hanford's tanks.

Response DOE and Ecology acknowledge the preference expressed in the comment and will take this preference and other public comments into consideration when making a final decision on remediating the TWRS waste. Removing, treating, and disposing of the tank waste would be the first step in providing protection to the vadose zone, groundwater, and the Columbia River. Please refer to the response to Comment numbers 0076.02, 0040.01 and 0005.18 for more information. The response to Comment number 0009.16 contains a discussion of the analysis of cost alternatives.

Specific Preference for Vitrification

Comment Number 0047.01

Ahouse, Loretta

Comment The wastes that are in the tank farms at Hanford must be dealt with at all costs. My preference is to see that all of the tank waste be removed and vitrified, regardless of whether or not the vitrified logs are ever moved to Yucca Mountain, Nevada.

It is an undisputed fact that the tanks at Hanford have leaked, although there appears to be a question of how far and how fast. Despite this, we do know that the tanks leak and may pose a potential danger to the groundwater under the Hanford site, and ultimately the Columbia River. For this reason, all of the waste that is technically feasible to remove, must be removed and immobilized in a safe manner. This should not be an issue of costs.

Response DOE and Ecology acknowledge the preference expressed in the comment and will take this preference and other public comments into consideration when making a final decision on remediating the TWRS waste. Please refer to the response to Comment number 0040.01 for a discussion of factors influencing the evaluation of alternatives. As more information becomes available from the ongoing vadose zone and groundwater monitoring and characterization program, DOE will be able to address issues related to tank farm closure. The EIS has been modified to include information on vadose zone contamination in Volume One, Sections 4.2 and 5.13 and in Volume Five, Appendix K. Vadose zone contamination is also discussed in the response to Comment number 0012.15.

Comment Number 0047.02

Ahouse, Loretta

Comment I do not agree with any plans which would leave a portion of the waste behind in the underground tanks.

Response DOE and Ecology acknowledge the preference expressed in the comment and will take this preference and other public comments into consideration when making a final decision on remediating the TWRS waste. Please refer to the response to Comment number 0040.01 for a discussion of factors influencing the evaluation of alternatives.

The preferred alternative assumes 99 percent retrieval of the tank waste. In a separate NEPA review, DOE intends to consider alternatives to tank farm closure. The EIS analysis addresses a range of alternatives that includes leaving all or a portion of HLW onsite, as well as alternatives that retrieve from the tanks as much waste as practicable (assumed to be 99 percent). Decisions associated with the

extent of retrieval will be supported by the TWRS EIS; however, the decisions on closure are not within the scope of the TWRS EIS. Please refer to the response to Comment numbers 0005.18 (assumption used in analysis of alternatives), 0072.08 (a discussion of closure), and 0072.05 (NEPA requirements for analysis of alternatives).

Comment Number 0079.02

Knight, Page

Comment One of the proposal alternatives is to take wastes from only from the double-shell tanks which are not yet leaking, vitrify them, and fill the single-shell tanks with sand and in effect walk away. This would possibly push the liquid waste deeper into the ground, hastening the contamination flow to the groundwater, and thus to the Columbia River. Presently, at the T tank farm, plutonium has become bound up in chemicals of the tank waste, and is moving rapidly toward groundwater. This is an inkling of what is to come in the next 100 years if the waste is left in the tanks. This is thus, an unacceptable alternative.

Response DOE and Ecology acknowledge the preference expressed in the comment and will take this preference and other public comments into consideration when making a final decision on remediating the TWRS waste. Please refer to the response to Comment number 0040.01 for a discussion of factors influencing the evaluation of alternatives. The TWRS EIS addresses the management, retrieval, treatment, and disposal of the tank waste and does not address closure of tank farm residuals, equipment, or soil contamination. For the purposes of this EIS, closure as a landfill was assumed, but this closure assumption contained in the EIS will not be used to identify a closure alternative in the TWRS ROD. Closure will be addressed in future NEPA documents. Please refer to response to Comment number 0072.05 for additional closure information.

DOE and Ecology remain committed to protecting the groundwater beneath the Hanford Site and the Columbia River. The EIS analyzes the impacts to groundwater associated with each of the alternatives in Volume One, Section 5.2 and Appendix F. The Final EIS has been modified to include a discussion of emerging data on vadose zone contamination beneath the tank farms. This discussion is provided in Volume Five, Appendix K. Please refer to the response to Comment number 0076.02.

L.3.4.1.2 General Preferences

Miscellaneous Preferences Related to Remediation

Comment Number 0009.03

Broderick, John J.

Comment Over the past decade, Hanford has demonstrated that it can not complete a project that takes a long time to construct. Grout, the new tank farm and HWVP come to mind in this regard, but there are many others. The many canceled projects have spent hundreds of millions of dollars with nothing to show for the effort. Each time there seems to be a good reason to cancel - but the percentage of canceled projects is very high. For this reason, the remediation of the tank waste must be done in facilities that can be constructed in a short period of time.

Response DOE and Ecology acknowledge the preference expressed in the comment and will take this preference and other public comments into consideration when making a final decision on remediating the TWRS waste. Please refer to the response to Comment number 0040.01 for a discussion of factors influencing the evaluation of alternatives. Volume One, Section 3.4 and Volume Two, Appendix B contain the implementation and completion schedule for each alternative. The Preferred Alternative identified in the EIS is consistent with the proposed remedy contained in the Tri-Party Agreement and the remediation schedule milestones in the Tri-Party Agreement. In addition, the existing schedule has been accelerated by approximately two years as a result of concurrent TWRS activities. Please refer to the response to Comment numbers 0009.10 and 0009.18 for a discussion of issues related to implementation of the preferred alternative, including projected construction completion dates. Please also refer to the response to Comment numbers 0055.06 and 0009.16 for a discussion of issues related to the consideration of cost in the alternatives analysis and the applicability of the HWVP to the preferred alternative.

Comment Number 0009.04

Broderick, John J.

Comment The National debt is increasing every year. There are strong pressures to reduce the deficit, and the debt itself. We have already seen the DOE budget drop substantially; and there are pressures to cut it even more. For this reason, the remediation of the tank waste must be done at the lowest possible price.

Response DOE and Ecology acknowledge the preference expressed in the comment and will take this preference and

other public comments into consideration when making a final decision on remediating the TWRS waste. Please refer to the response to Comment number 0040.01 for a discussion of factors influencing the evaluation of alternatives. DOE and Ecology believe that there is a potential to reduce the cost for tank waste remediation by allowing the market place to establish, through the competitive bidding process, the cost for waste treatment. Please refer to the response to Comment number 0036.15 for more information. The environmental impact of all factors analyzed during the evaluation of each alternative included in the EIS is presented in Volume One, Table 5.14.1.

Comment Number 0014.03

Bullington, Darryl C.

Comment Further proposals of hazardous chemical processes based upon unproven technology using insupportable assumptions such as a ninety-nine percent retrievability of sludge to generate so much high-level waste that it can not be safely contained in existing repositories continues to erode any credibility that may yet exist between the DOE and the public. Such reports not only wasted resources, they assure continued inaction and indecision.

Response DOE and Ecology acknowledge the preference expressed in the comment and will take this preference and other public comments into consideration when making a final decision on remediating the TWRS waste. Please refer to the response to Comment number 0040.01 for a discussion of factors influencing the evaluation of alternatives. For each of the alternatives, technical uncertainties were addressed in Volume One, Section 3.4 and Volume Two, Appendix B. For the Final EIS, Volume Five, Appendix K was added to the EIS to consolidate discussion of uncertainties associated with the analysis of environmental and human health impacts. The EIS also analyzes alternatives involving retrieval of less than 99 percent of the tank waste. These alternatives include the in situ alternatives which would involve minimal waste retrieval and the ex situ/in situ combination alternatives which would involve partial waste retrieval. For more information regarding the 99 percent retrieval assumption, please refer to the response to Comment numbers 0005.18 and 0089.07. Please also refer to response to Comment numbers 0069.04 and 0037.03 for issues related to regulatory compliance requirements associated with disposal of tank waste and geologic repository availability.

Comment Number 0021.01

Shilling, Fred E.

Comment Our concerns regarding the storage of nuclear wastes at Hanford: some of the stuff is leaking and it was not supposed to; some of it presents the threat of explosion, and it was not supposed to; some sort of omnibus cleanup was supposed to be under way by now but it is not; all the while the costs keep escalating while axe grinders argue for use of the plutonium for fuel for their profit and our disposal problem. And there is still no safe disposal.

Response DOE and Ecology acknowledge the preference expressed in the comment and will take this preference and other public comments into consideration when making a final decision on remediating the TWRS waste. The TWRS EIS was initiated because DOE needs to manage and dispose of tank waste to "reduce existing and future risk to the public, Site workers, and the environment" (Draft TWRS EIS, Section 2.0). The EIS addresses the DOE proposed action to manage and dispose of tank waste, as well as a range of reasonable alternatives. The use of plutonium for fuel is beyond the scope of this EIS. For each alternative, the EIS analyzes potential impacts to the human and natural environment including potential impacts from future releases to groundwater in Volume One, Section 5.2, releases to the air in Section 5.3, impacts to ecological and biological resources in Section 5.4, impacts to human health in Section 5.11, and impacts from explosions and other accidents in Section 5.12. Each of the alternatives, except No Action and Long-Term Management identify how tank waste would be disposed of. For HLW retrieval from the tanks, disposal would be offsite in the proposed geologic repository. For discussion of waste disposal under each alternative see Volume One, Section 3.4, and Appendix B.

Comment Number 0026.01

Blazek, Mary Lou

Comment I see three long-term strategic hazards that must be considered:

1. prevention of dispersal into the environment
2. prevention of direct human exposure (i.e., Site workers, etc.)
3. prevention of misappropriation by terrorist/criminal groups.

These concerns are not limited to high-grade plutonium.

Response DOE and Ecology acknowledge the preference expressed in the comment and will take this preference and other public comments into consideration when making a final decision on remediating the TWRS waste. Please refer to the response to Comment number 0040.01 for a discussion of factors influencing the evaluation of alternatives. Please also refer to the response to Comment number 0021.01 for a discussion of EIS analysis regarding disposal of water into the environment. Prevention of direct human exposure is addressed for each alternative in Volume One, Section 3.4, and Appendix B. All alternatives would provide for appropriate security to minimize the risk of misappropriation.

Comment Number 0026.02

Blazek, Mary Lou

Comment I believe there are reasons to select a variety of processes in management. Some elements will be best served by vitrification, and others by simple long-term storage. I see no reason why at least a portion of the waste should not be stored at ground level, where it can be adequately monitored for leakage or casket deterioration and repackaged as indicated.

Response DOE and Ecology acknowledge the preference expressed in the comment and will take this preference and other public comments into consideration when making a final decision on remediating the TWRS waste. The bounding approach to the evaluation of reasonable alternatives provides the option for the decision makers to select a variety of processes in the ROD. The EIS range of alternatives included retrieval from zero to 99 percent of the waste, as well as a discussion of those technologies currently available for retrieval, separations, and immobilization. In addition, the EIS addresses four alternatives (i.e., ISV, In Situ Fill and Cap, and Ex Situ/In Situ Combinations 1 and 2) that include storage and/or disposal of all or part of the waste near surface onsite.

Risks to human health associated with transportation of HLW to the proposed geologic repository were analyzed and compared for each alternative in the accident scenarios discussed in Volume One, Section 5.12, and Volume Four, Appendix E. This analysis in conjunction with the analysis of risks associated with onsite disposal versus offsite disposal of HLW, supports the comparison of alternatives. Long-term risk to human health and the environment specific to onsite and offsite storage and risks in general were discussed in Volume One, Section 5.11 and Volume Three, Appendix D. All ex situ alternatives, except for the Ex Situ No Separations alternative, specify that the LAW be stored onsite in a near surface vault and that the remaining HLW be stored onsite pending disposal at the proposed geologic repository. The Ex Situ No Separations alternative would result in offsite disposal of the tank waste. Please refer to the response to Comment numbers 0026.01 and 0072.05.

Comment Number 0026.03

Blazek, Mary Lou

Comment In general I do not favor transfer to other sites. I believe the actual transfer would often times be hazardous, I see no advantage to deep burial over surface interment, and it is generally viewed as a means of "getting it out of my backyard" with all the political overtones and delays involved.

Response DOE and Ecology acknowledge the preference expressed in the comment and will take this preference and other public comments into consideration when making a final decision on remediating the TWRS waste. Please refer to the response to Comment number 0026.01 for discussion of the analysis of impacts in the EIS, and 0026.02 for a discussion of a comparison of alternatives relative to onsite verses offsite disposal.

Comment Number 0026.04

Blazek, Mary Lou

Comment I see a need for use of a variety of separation/purification techniques, a variety of storage techniques, and a sense of urgency to start the process. We have spent far too long on looking for a single perfect solution and site. Technology will change over the next 50-100 years, and we can neither wait for that to happen nor insist on locking ourselves into a single process.

Response Please refer to the response to Comment numbers 0026.01, and 0026.02 for a discussion of the range options available for the decision makers based on the EIS analysis and the response to Comment number 0072.05 for discussion of NEPA requirements for analysis of a range of alternatives. The response to Comment number 0076.03 addresses modification to technologies over time, and the response to Comment number 0009.01 discusses technology optimization and the urgency associated with tank waste remediation.

Comment Number 0032.02

Heacock, Harold

Comment The continued management and minimum waste retrieval alternatives are not acceptable solutions to a major environmental problem since they do not include the retrieval of waste from the single-shell tanks.

We believe that any tank waste remediation program must include removal and processing the waste to an acceptable solid in order to eliminate the environmental threats resulting from any retention of the waste in tanks of questionable integrity and lifetime.

Response DOE and Ecology acknowledge the preference expressed in the comment and will take this preference and other public comments into consideration when making a final decision on remediating the TWRS waste. Please refer to the response to Comment number 0040.01 for a discussion of factors influencing the evaluation of alternatives.

The EIS analysis presents data to support a comparison of the potential environmental impacts form retention of waste in the tanks (No Action and Long-Term Management alternatives) verses various waste management and disposal strategies represented by the other alternatives analyzed in the EIS. Please refer to the response to Comment numbers 0026.01 and 0026.02 for more information.

Comment Number 0034.02

Belsey, Richard

Comment So there are real compelling reasons to do the one thing that will most increase the safety and health issues for workers, people, and the environment. And that is this material needs to be stabilized so it does not and cannot move.

Response DOE and Ecology acknowledge the preference expressed in the comment and will take this preference and other public comments into consideration when making a final decision on remediating the TWRS waste. Please refer to the response to Comment number 0040.01 for a discussion of factors influencing the evaluation of alternatives. Please refer to response to Comment numbers 0026.01, 0026.02, and 0072.05 for a discussion of the range of alternatives addressed in the EIS, including alternatives involving immobilization of all or portions of the waste.

Comment Number 0034.03

Belsey, Richard

Comment Waste management side there are compelling reasons too. Interestingly they are dollars. The cost of sitting or baby-sitting these tanks is the most frustrating thing that I can think of.

It costs -- has costs anywhere from 200 to 300 million dollars a year. Finally, the people in the Tank Waste Remediation System are beginning to bring this mortgage down by a variety of techniques, but it is still the largest single overhead -- and I put it in as overhead because it does not produce any cleanup.

It does not produce any movement. Those resources are needed to do actual cleanup work. And the meter is running. As we sit here, the meter runs every single day.

Response DOE and Ecology acknowledge the preference expressed in the comment and will take this preference and other public comments into consideration when making a final decision on remediating the TWRS waste. Please refer to the response to Comment number 0040.01 for a discussion of factors influencing the evaluation of alternatives. Reduction in mortgage costs associated with continued management of tank waste was accounted for in the cost estimates for each alternative analyzed in the EIS. The No Action alternative cost estimate represents the 100-year mortgage for tank waste management. Please refer to the response to Comment number 0009.16, which discusses the methods by which cost was incorporated into the alternative analyses.

Comment Number 0034.04

Belsey, Richard

Comment And these were because people knew or had learned about the problems in the tanks, and they wanted to do something about it. This was an intense five or six-month period. And the Tank Waste Task Force came out and said we have to change what we were doing. We need to put both the high-low-level activity fractions into glass, different kinds of glass.

Response DOE and Ecology acknowledge the preference expressed in the comment and will take this preference and other public comments into consideration when making a final decision on remediating the TWRS waste. Please refer to the response to Comment number 0040.01 for a discussion of factors influencing the evaluation of alternatives. The approach to tank waste identified in the Comment is represented in the EIS in the various ex situ alternatives presented in Volume One, Section 3.4. The ex situ alternatives provide for varying Volumes of low-activity verses HLW to be vitrified based on the level of separations (i.e., from separations to extensive separations).

Comment Number 0034.06

Belsey, Richard

Comment And I say all of this because -- as background to the fact that the committee and the board now has supported the alternative path as the one that is most likely to meet the needs of the Tri-Party Agreement, not the milestones.

The milestones are just indicators of how you are working on health and safety issues, moving toward the ultimate first step, the biggest step, which is taking it from being in a soluble form which can migrate into the ground, into the groundwater, into the Columbia River, and stabilizing that so it will keep in place for thousands of years.

Response DOE and Ecology acknowledge the concern expressed in the comment. DOE and Ecology are fully committed to the intent, as well as the milestone requirements in the 1994 Tri-Party Agreement and amendments to the Tri-Party Agreement.

Comment Number 0074.01

Sims, Lynn

Comment I think one of the issues here is that this project that we're talking about is probably the largest civil works project, the most expensive, and the most dangerous project ever attempted by mankind in history. And we're all very concerned about it and want to do the best we can to make it work. And that's, everybody is emotionally involved with this, and there might not be any good solutions, except to try to keep it out of the water, out of the Columbia River.

Response DOE and Ecology acknowledge the preference expressed in the comment and will take this preference and other public comments into consideration when making a final decision on remediating the TWRS waste. Please refer to the response to Comment number 0040.01 for a discussion of factors influencing the evaluation of alternatives and the response to Comment number 0026.02 for a discussion of impacts analyzed in the EIS, including impacts to groundwater and the Columbia River.

Preferences Related to Tank Waste Removal

Comment Number 0012.02

ODOE

Comment Oregonians oppose all tank waste options which leave significant amounts of waste in Hanford tanks. The cumulative impacts from all of the past activities at Hanford on public health and safety, the environment and the Columbia River make it inappropriate to consider leaving any of the tank wastes in place. The Northwest has shouldered more than a fair share of the cold war burden and its legacy. Hanford's cleanup mission must proceed.

Response DOE and Ecology acknowledge the preference expressed in the comment and will take this preference and other public comments into consideration when making a final decision on remediating the TWRS waste. Please refer to the response to Comment number 0040.01 for a discussion of factors influencing the evaluation of alternatives. Cumulative impacts from the TWRS alternatives and other proposed or reasonably foreseeable related actions are presented in Volume One, Section 5.13.

Comment Number 0012.04

ODOE

Comment The other alternatives under consideration leave most or all of the wastes in the tanks. With the exception of in situ vitrification, which is an undeveloped and unproven technology, other alternatives do little to remove the hazards posed by the wastes. To reduce the risks to people, these alternatives would require permanent closure of Hanford lands to other uses. Sacrificing Hanford in this way does not adequately reduce the harm and risks to the environment or to future generations. For these alternatives, the risk analyses in the EIS show massive plumes of radioactive material slowly moving across the Hanford site and into the Columbia River for hundreds to thousands of years.

Response DOE and Ecology acknowledge the preference expressed in the comment and will take this preference and other public comments into consideration when making a final decision on remediating the TWRS waste. Technical uncertainty of undeveloped or unproven technology, and the long-term risk associated with the various alternatives were factors analyzed by DOE and Ecology for each alternative. This information is presented in Volume One, Section 5.4. Please refer to the response to Comment number 0040.01 for a discussion of factors influencing the evaluation of alternatives. As stated in Volume One, Section 3.3, decision on closure of the tank farms will be made in the future. Additional analysis will be performed at that time concerning any additional measures that need to be taken to protect the groundwater and its future potential users. The TWRS EIS addresses the management, retrieval, treatment, storage, and disposal of the tank waste and does not address final remediation of the tank farm residuals, equipment, or soil contamination. For more information on closure, please refer to the response to Comment number 0072.08.

Comment Number 0012.05

ODOE

Comment Cost should not be the sole or even predominant criteria used to select among the alternatives. The first criteria that must be applied is protection of public health and safety and the environment. This criteria eliminates all of the alternatives which leave all or part of the waste in the tanks, except in situ vitrification. The EIS claims a lower risk for in situ vitrification, but because in situ vitrification technology is uncertain, the potential for failure is unacceptably high. We strongly oppose all of the alternatives which leave the waste in Hanford's tanks.

Also, the cost analyses do not include the lost value of the lands or the costs from harm to future generations or the environment. Ultimately, the costs of these alternatives would prove to be much greater than removing and cleaning up the wastes, as called for by the preferred alternative.

Response DOE and Ecology acknowledge the preference expressed in the comment and will take this preference and other public comments into consideration when making a final decision on remediating the TWRS waste. Volume One, Section 5.12 contains discussions of accident risk for each alternative. The EIS discusses long-term loss of land use and immediate and potential future risks to human health impacts. Neither is analyzed in terms of cost because a dollar value to human life and the land cannot be assumed.

Cost and risk to human health and the environment were several factors analyzed by DOE and Ecology for each alternative. Assessing the economic impact due to lost land value or harm to future generations other than health impacts or the environment were beyond the scope of this EIS and were not considered. Each impact was analyzed using a consistent methodology. The results were objectively presented in the EIS for the public and the decision makers. DOE and Ecology are committed to the Tri-Party Agreement requirement that no residual volume greater than 1 percent remain in the given tank, unless this requirement is not technically achievable.

Comment Number 0037.01

Eldredge, Maureen

Comment The risks in this EIS show clearly that the only responsible option is retrieving all the waste. This needs to start happening now.

Response DOE and Ecology acknowledge the preference expressed in the comment and will take this preference and other public comments into consideration when making a final decision on remediating the TWRS waste. Please refer to the response to Comment number 0021.01.

Comment Number 0073.01

Yazzolino, Brad

Comment I simply wanted to put this in perspective, in the sense that I'm in the art world. The art world is basically lasts for thousands of years in the same sense that the radioactivity does. And I've been immersed in the geology of the Hanford area for the last year or so, and some other aspects about the river. And basically you need to remove the radioactive material from its proximity to the river because in fact that river valley has been there for about 21 million years. And it's going to persist in that area, and it's going to eventually wash your radioactivity to the sea, and spread it all over the river valley if you leave it there. It needs to be removed.

Response DOE and Ecology acknowledge the preference expressed in the comment and will take this preference and other public comments into consideration when making a final decision on remediating the TWRS waste. The long-term impacts associated with tank waste alternatives, including impacts for alternatives that would leave all or part of the waste in place in the tanks and others that would retrieve the greatest extent of waste practicable, were among the factors analyzed in the EIS. This analysis included human health and groundwater impacts that were calculated to 10,000 years in the future, as well as impacts associated with climate changes that potentially would result in the situation described in the comment. The response to Comment numbers 0012.01 and 0012.15 discusses the impact of past tank leaks and current efforts to determine the extent to which these leaks have impacted the area beneath the tanks.

Comment Number 0090.04

Postcard

Comment Please listen to us say no:

to leaving High-Level Nuclear Waste in our ground.

Response DOE and Ecology acknowledge the preference expressed in the comment and will take this preference and other public comments into consideration when making a final decision on remediating the TWRS waste. Please refer to the response to Comment number 0026.02 for a discussion of the extent to which each of the alternatives would result in onsite disposal of HLW.

Comment Number 0091.02

Dyson, Jessica

Comment It is time to stop being in denial and start making public safety your utmost concern. In doing so, you must follow the Tri-Party Agreement and vitrify all the waste in the tank and it is not acceptable to leave any waste in the tank because that could pose a danger to the public in the future.

Response DOE and Ecology acknowledge the preference expressed in the comment and will take this preference and other public comments into consideration when making a final decision on remediating the TWRS waste. The DOE and Ecology preferred alternative, Phased Implementation, would comply with the requirement of the Tri-Party Agreement. As indicated in Volume One, Section 2.0, the underlying need for action is to "reduce existing and potential future risk to the public, Site workers, and the environment." DOE also must take action to "ensure compliance with Federal and Washington State laws regulating the management and disposal" of the tank waste and the cesium and strontium capsules. These underlying needs for the proposed action are also the basis for the continued management of the tank waste by the TWRS program, as described in Volume One, Section 3.2. Please refer to the response to Comment number 0026.02 for a discussion of the extent to which each alternative would retrieve waste from the tanks.

Preferences Related to Privatization

Comment Number 0014.04

Bullington, Darryl C.

Comment If Congress is really serious about containing existing hazardous wastes along with adequate monitoring and emergency planning it should set aside funds in separate easily identified accounts which are not subject to whatever political whim that comes along to be used exclusively to:

1. Identify the size of all waste streams from all anticipated future sources and then establish a final repository sufficiently large to accommodate the demand for storage as required.
2. Monitor the integrity of all existing tanks and establish plans and funds to reduce the danger of further leakage including emergency plans should further leakage occur.
3. Reduce the options for safely confining stored wastes to several that can be achieved in the time frame established using existing technology and involving a minimum of time consuming and costly research and development. Chosen methods should have a high probability of accomplishing all milestones with the least risk to the public and the workers involved. Funds should also be set aside for insurance purposes should accidents occur. Safety of the public and the environment should take precedence over providing jobs or solving other social needs. These few alternatives, assuming that all the 50,000 curies of plutonium can be excluded from the biosphere, should then be contrasted with the do-nothing alternative. The report should show the costs and consequences of each alternative including a discussion of accidents that may occur along the entire pathway until confinement.

Response The purpose of this EIS is to present and analyze the range of reasonable alternatives that are available to remediate the tank waste at Hanford. Please refer to the response to Comment number 0072.05. DOE Richland Operations Office prepares a budget each year, which includes requests for funds used for cleanup; however, only

Congress has the authority to appropriate funds. Congressional funding issues were not included in the scope of this EIS.

There are several ongoing activities involved with collecting and analyzing data on tank contents. Tank inventory data are presented in Volume Two, Appendix A (Tables A.2.1.1, A.2.1.2, and A.2.1.3), and waste projections for future tank waste additions are shown in Table A.2.4.1. Please refer to the response to Comment numbers 0012.14 and 0072.07 for a discussion of the tank waste inventory and characterization methods planned or currently under way.

Establishing a final repository is not included in the scope of this EIS; however, for the purposes of analyzing the alternatives presented in this EIS, a potential geologic repository candidate site at Yucca Mountain, Nevada was assumed to be the final disposal site. A discussion of the requirement for HLW disposal in a geologic repository is provided in Volume One, Section 6.2.

The TWRS program also includes monitoring the integrity of tanks and characterizing the vadose zone around the tank farms to detect leaks. DOE also conducts numerous activities to provide continued safe storage of the tank waste, and emergency plans have been developed and are in place. Descriptions of ongoing programs and tank safety issues are presented in Volume One, Section 3.2 and Volume Two, Appendix B, respectively. All monitoring and safety programs (Section 3.4) would continue through remediation. DOE is required to mitigate all accidents involving releases to the environment and Volume One, Section 5.20 identifies potential mitigation measures that could be implemented to alleviate the environmental impacts of the alternatives.

A range of reasonable alternatives was analyzed for the TWRS EIS, including the No Action alternative and alternatives involving extensive retrieval. Please refer to the response to Comment number 0040.01 for a discussion of factors influencing the evaluation of alternatives. The purpose of the EIS is to present the results of impact analyses in the most objective manner possible. These results will also be used by the decision makers to select an alternative and prepare the ROD. Volume One, Section 3.7 and Volume Two, Appendix B contain summary discussions of the alternatives comparisons. The Summary, Section S.7 contains an alternatives comparison, based on impact type and Volume One, Section 5.14 summarizes the environmental impacts of each alternative.

Comment Number 0017.01

Fisk, Charles P.

Comment Given Westinghouse's, Battelle's, etc. dismal performances, I certainly would <u>not</u> recommend privatization! Government created the mess and government should accept cost of remediation, <u>not</u> some for-profit corporation.

Response DOE and Ecology acknowledge the recommendation expressed in the comment. Although the contracting strategy known as privatization is not addressed in the EIS, the discussion of the Phased Implementation alternative does address the technical strategy of an incremental approach to tank waste remediation. Please refer to Volume One, Sections 3.3 and 3.4 of the EIS for more information on alternatives implementation and the Phased Implementation alternative.

Comment Number 0017.02

Fisk, Charles P.

Comment The "preferred alternative" is full of holes, as HEAL has persuasively analyzed far better than I can.

Response DOE and Ecology acknowledge the preference expressed in the comment and will take this preference and other public comments into consideration when making a final decision on remediating the TWRS waste. Please refer to the response to Comment number 0040.01 for a discussion of factors influencing the evaluation of alternatives and the response to Comment number 0009.19 for reasons Phased Implementation is the identified preferred alternative.

Comment Number 0017.03

Fisk, Charles P.

Comment The entire amount of waste needs to be vitrified, not just 25 percent of it, regardless of the cost. If, as Republicans propose, we could afford a continuation of "Star Wars", we can be assuredly cancel that wasteful idea and put the money into a completed and thorough clean up of the mess.

Response DOE and Ecology acknowledge the preference expressed in the comment and will take this preference and other public comments into consideration when making a final decision on remediating the TWRS waste. Cost was one factor analyzed by DOE and Ecology for each of the alternatives. Please refer to the response to Comment number 0040.01 for a discussion of factors influencing the evaluation of alternatives. For a discussion of the extent to which each alternative would result in waste retrieval and/or treatment please refer to the response to Comment number 0026.02. DOE and Ecology note that the preferred alternative would result in remediation of all waste practicably or no less than 99 percent.

Comment Number 0017.04

Fisk, Charles P.

Comment We have the technology for vitrification; now get with it and DO IT! The Columbia River deserves maximum protection as soon as possible.

Response DOE and Ecology acknowledge the preference expressed in the comment and will take this preference and other public comments into consideration when making a final decision on remediating the TWRS waste. DOE and Ecology are committed to protecting the Columbia River. The response to Comment number 0012.01 addresses groundwater contamination and vadose zone characterization and monitoring. Please also refer to the response to Comment number 0072.05 for discussion of the approach to analyzing alternatives and technologies in the EIS.

Comment Number 0060.01

Davenport, Leslie C.

Comment I support the preferred Phased Implementation alternative, but with some changes; primarily that only one separations/LAW/HLW processing facility be built by a private contractor during Phase 1. The primary reason for this choice is that it can meet the Tri-Party Agreement and yet result in the minimization of overall costs and ultimately facilities needing decontamination and disposal. Whether additional separations should remove technetium, cesium, strontium, and TRU elements should be left to engineering judgement, dependent primarily on meeting required LAW product specifications for disposal onsite in near-surface retrievable disposal vaults. The other primary consideration would be to ensure that interim and final disposition methods for TRU elements always are critically safe.

Response DOE and Ecology acknowledge the preference expressed in the comment and will take this preference and other public comments into consideration when making a final decision on remediating the TWRS waste. Please refer to the response to Comment number 0040.01 for a discussion of factors influencing the evaluation of alternatives. DOE and Ecology remain committed to compliance with the Tri-Party Agreement under which the general requirements for the preferred alternative were renegotiated in 1994. Specific separations technologies will be evaluated during the detailed design phase that will follow the final remedy selection and the ROD. Separation technologies, along with removal and immobilization technologies, will be tested during the demonstration phase (Phase 1).

Comment Number 0078.07

ODOE

Comment USDOE must move forward with cleanup as quickly as possible. USDOE must commit to remove all the waste from the tanks and convert it to a durable and stable waste form. The privatization alternative is the only alternative of the four acceptable alternatives that can be done soon. All of the others will involve extensive delays.

Response DOE and Ecology acknowledge the preference expressed in the comment and will take this preference and other public comments into consideration when making a final decision on remediating the TWRS waste. Please refer to the response to Comment numbers 0072.05, 0076.03, and 0009.19.

Miscellaneous Preferences Related to the Alternatives

Comment Number 0032.03

Heacock, Harold

Comment We also do not believe the technical feasibility of several of the in situ treatment processes has been demonstrated adequately to seriously consider them as viable alternatives.

Response DOE and Ecology acknowledge the preference expressed in the comment and will take this preference and other public comments into consideration when making a final decision on remediating the TWRS waste. Please refer to the response to Comment number 0040.01 for a discussion of factors influencing the evaluation of alternatives. ISV is a relatively new process that has not been tried at this scale previously, but was considered a potentially viable alternative. Implementability issues for each of the alternatives are discussed in Volume One, Section 3.4 and Volume Two, Appendix B. Please refer to response to Comment numbers 0072.10 and 0072.80 for information on NEPA requirement to consider reasonable alternatives in the EIS.

Comment Number 0035.02

Martin, Todd

Comment It continues to debate issues that have long been laid to rest, such as what is the waste form that we will use at Hanford. The preferred alternative does not mandate the glasses used. It does not mandate vitrification. It should. We have made that decision. Let's go forward.

Response DOE and Ecology acknowledge the preference expressed in the comment and will take this preference and other public comments into consideration when making a final decision on remediating the TWRS waste. Vitrification and glass-types were analyzed for the HLW disposal; however, DOE and Ecology have identified the treatment process for the LAW as immobilization rather than vitrification for the Phased Implementation alternative. As identified in Volume One, Section 3.4 and Volume Two, Section B.3 of the EIS, LAW would be processed using a technology that would meet LAW specifications. These specifications would be performance based, using vitrification as a benchmark, and would have specific requirements for size, chemical composition limits, isotopic content, and physical parameters. Even though the Tri-Party Agreement suggests that certain decisions have been made, NEPA requires an objective analysis of all reasonable alternatives. Please refer to the response to Comment numbers 0060.02, 0005.07, and 0034.05.

This approach to LAW treatment is consistent with the Tank Waste Task Force (HWTF 1993) recommendation to use the most practicable, timely, available technology, while leaving room for future innovation. All HLW removed from the tanks and that remains after separations will be vitrified under the preferred alternative. Please refer to the response to Comment number 0009.19 for a discussion of the reasons Phased Implementation is identified as the preferred alternative.

Comment Number 0036.09

HEAL

Comment HEAL supports the preferred alternative's pretreatment process.

The TWRS Task Force values on pretreatment are explicit and strongly held. According to the TWRS Task Force Final Report:

The high cost and uncertainty of high-tech pretreatment and R&D threatens funding for higher performance low-level waste forms, vitrification, and cleanup. Use the most practicable, timely, available technology, while leaving room for future innovation. Keep a folio of technological options and make strategic investments over time to support a limited number of promising options. Give up further research on unlikely options (TWTF p. 11)

The intermediate separations case is response to this value (although the difficult challenge of technetium removal in the Phased Implementation alternative is a concern). HEAL strongly opposes any movement toward an extensive separations pretreatment technology.

Response DOE and Ecology acknowledge the preference expressed in the comment and will take this preference and other public comments into consideration when making a final decision on remediating the TWRS waste. Please refer to the response to Comment number 0098.02.

Comment Number 0046.04

DiGirolamo, Linda Raye

Comment Yes, encase in glass and bury this "CRUD" and more importantly... Stop all future plutonium fuel rod production at once. New Age Energy must be embarked upon at once to save man and the earth.

Response DOE and Ecology acknowledge the preference expressed in the comment and will take this preference and other public comments into consideration when making a final decision on remediating the TWRS waste.

Comment Number 0059.01

James Jordan Associates

Comment JJA recommends that the Environmental Impact Statement include in its analysis an alternative concept invented by Drs. Morris Reich, James Powell, and Robert Barletta of Brookhaven National Laboratory for the safe immobilization and isolation from-the-environment radioactive waste. This novel concept has the potential of being the safest, least costly, and most expeditious method for the disposal of the various radioactive wastes currently stored in the underground storage tanks at Hanford, including, if desired, the vitrification of the cesium and strontium capsules located at the Hanford Site.

This system which uses modular canisters with integral vitrification capability does not require an upgrade to the tank farm waste transfer system. This system will not require the construction of extensive buried transfer lines that is included in all of the alternatives except the No Action alternative. Indeed, the elimination of the complex tank farm waste transfer system significantly reduces the potential for short-term impacts of human health and the environment. Using modular canisters with integral vitrification provides for a dramatic reduction in the risk of long-term impacts on the public health and the environment in that the system does not have a large central vitrification facility to deactivate and dispose of at the end of the vitrification campaign. Compared to a conventional vitrifier, the in-can vitrifier does not require the pouring of molten radioactive glass.

Response DOE and Ecology acknowledge the preference expressed in the comment and will take this preference and other public comments into consideration when making a final decision on remediating the TWRS waste. The Draft EIS addressed the full range of reasonable alternatives. The alternative identified in the comment is bounded by the alternatives addressed in the Draft EIS. DOE and Ecology therefore believe that including the requested alternative would not provide valuable additional information to the public or decision makers. Please refer to the response to Comment numbers 0072.05, 0072.79, and 0097.01.

Comment Number 0060.02

Davenport, Leslie C.

Comment Both continued management alternatives are unacceptable for the long term.

The Minimal Waste Retrieval (In Situ) alternatives do not meet waste disposal laws, regulations, and policies and I feel are unacceptable in the long term. The In Situ Fill and Cap would not immobilize the wastes, only fill the tanks with gravel (creating more contaminated waste) and keep it all onsite in a form that would eventually leach to the groundwater. The In Situ Vitrification alternative is interesting and perhaps could be used on some of the small Multiple Underground Storage Tanks (MUSTs) that contain lower amounts of radioactivity, but the degree of technical uncertainty is too high to consider application to an entire tank farm of up to 20 tanks at once. Verifying that all tanks are completely vitrified down to 60 ft below the ground surface is nearly impossible, and there is no way to immobilize radionuclide plumes below the leaking SSTs.

Response DOE and Ecology acknowledge the preference expressed in the comment and will take this preference and other public comments into consideration when making a final decision on remediating the TWRS waste. Please refer to the response to Comment number 0040.01 for a discussion of factors influencing the evaluation of alternatives. NEPA requires that an EIS address the full range of reasonable alternatives, including alternatives that would not comply with laws and regulations. The TWRS EIS addresses 10 alternatives for tank waste, ranging from No Action to extensive retrieval, and four alternatives for the cesium and strontium capsules. Please refer to the response to Comment numbers 0072.80 and 0072.10 for a discussion of the NEPA requirement to include a No Action alternative in the EIS analyses.

Comment Number 0060.03

Davenport, Leslie C.

Comment The partial waste retrieval alternatives do not meet waste disposal laws, regulations, and policies because they would retrieve only 90 percent or less of the radionuclides. I feel they will be deemed unacceptable in the future, thereby necessitating additional future operations to finish the job.

Response DOE and Ecology acknowledge the concerns presented in the comment. DOE and Ecology remain committed to compliance with the Tri-Party Agreement, which requires removal of all technically achievable waste or no less than 99 percent of the waste from each tank. Please refer to the response to Comment number 0060.02 and for discussions of the NEPA requirement to address a range of alternatives including alternatives that do not comply with regulations. Refer to the response to Comment numbers 0072.80 and 0072.10.

Comment Number 0060.04

Davenport, Leslie C.

Comment The extensive waste retrieval (ex situ) alternatives appear to be the only acceptable methods to deal with the approximately 200 MCi of radionuclides. However, the Ex Situ No Separations alternative appears to be too expensive because all tank wastes would be vitrified and/or calcined, resulting in too many high-level waste packages to ship to and store in a waste repository. The Ex Situ Intermediate and Extensive Separations alternatives are difficult to choose between, because the efficiency of the sludge washing, ion exchange, and multiple complex chemical separations processes are not fully known for the various types of tank wastes. Hence, those two alternatives should be compared in a pilot plant using a Phased Implementation (possibly along with the In Situ Vitrification alternative applied selectively, particularly for MUSTs, and SSTs that have not leaked).

Response DOE and Ecology acknowledge the preference expressed in the comment and will take this preference and other public comments into consideration when making a final decision on remediating the TWRS waste. Please refer to the response to Comment number 0040.01 for a discussion of factors influencing the evaluation of alternatives.

Technical evaluation, categorization of tank waste, and application of appropriate technology would be conducted during Phase 1 (demonstration phase) of Phased Implementation and during the detailed design phase of any alternative analyzed in the EIS. Volume One, Section 3.4 includes descriptions of the processes, cost, and Implementability for each tank waste alternative. Volume One, Section 5.14 provides a summary of the environmental impacts for each tank waste alternative. The EIS provides the basis for comparison among the alternatives identified. DOE and Ecology believe sufficient differentiation exists between the alternatives to support a decision on the alternative to be implemented; therefore, a demonstration phase comparison of the two alternatives would postpone remediation.

Comment Number 0072.10

CTUIR

Comment The Tri-Party Agreement mandates full retrieval as the goal; only if this is not practicable on a tank-by-tank basis can lower retrieval goals be negotiated. Therefore, the in situ alternatives are not allowed and did not have to be evaluated.

Response DOE and Ecology acknowledge the preference expressed in the comment and will take this preference and other public comments into consideration when making a final decision on remediating the TWRS waste. Please refer to the response to Comment number 0040.01 for a discussion of factors influencing the evaluation of alternatives.

As required by the CEQ, the TWRS Draft EIS identifies and analyzes a range of reasonable alternatives for the proposed action, including those that are "not within the jurisdiction" of the agency (40 CFR 1502.14). DOE guidance on NEPA requires that EIS alternatives be addressed even if there is "conflict with lawfully established requirements" (DOE 1993d). However, the Agency is required to identify the laws and regulations that apply to each alternative and indicate if the alternative, if selected for implementation, would comply with applicable laws and regulations. This information must be provided to the public and the decision makers. Therefore, the failure to comply with the Tri-Party Agreement is not sufficient basis for excluding an alternative from detailed analysis in the EIS (40 CFR 1502.2d). A discussion of the methods used to develop the alternatives in compliance with NEPA requirements is presented in the response to Comment number 0072.05. Please refer to the response to Comment numbers 0072.80 and 0072.52.

Comment Number 0072.16

CTUIR

Comment In situ alternatives were not necessary since they are not allowed under the Tri-Party Agreement.

Response Please refer to the response to Comment numbers 0072.10 , 0072.52, and 0072.80.

Comment Number 0076.03

Blazek, Mary Lou

Comment The preferred alternative relies on using proven technology, and using a phased approach. We think a learn as you go approach makes sense, given the history of Hanford. And that should identify problems earlier, and at smaller economic and environmental cost.

Response DOE and Ecology acknowledge the preference expressed in the comment and will take this preference and other public comments into consideration when making a final decision on remediating the TWRS waste. The Preferred Alternative would allow DOE to proceed with tank waste remediation. System modifications would be evaluated as waste inventory, removal method, separations, and disposal data are collected and analyzed during the Phase 1 demonstration. This continuous improvement is the cornerstone of the "learn and improve while doing" approach cited in the comment. Please refer to the response to Comment numbers 0060.04, 0060.02, and 0009.19 for more information on the preferred alternative.

Comment Number 0077.02

ODOE

Comment Leaving wastes in the tanks poses huge risks. The tanks are corroding and failing. As they fail, the radioactive waste is released to the soil and ultimately to the groundwater and to the Columbia River. Vitrifying the tank waste makes it far more stable and greatly reduces the threat to the public and the environment. While the cost of the preferred alternative is substantial, it is the only alternative which satisfactorily deals with the dangers presented by these wastes as quickly as practical. The phased approach allows USDOE to get on with cleanup while allowing for possible development of better approaches which remove all tank wastes.

Response DOE and Ecology acknowledge the preference expressed in the comment and will take this preference and other public comments into consideration when making a final decision on remediating the TWRS waste. Please refer to the response to Comment number 0040.01 for a discussion of factors influencing the evaluation of alternatives. Please also refer to the response to Comment numbers 0076.03 and 0060.04. The response to Comment number 0091.01 addresses protection of the Columbia River in relation to the preferred alternative.

Comment Number 0078.02

ODOE

Comment Unacceptable Alternatives

The EIS evaluates the alternatives USDOE believes are available for the tank waste. Four alternatives are unacceptable because they could allow exposures to the environment and the public at levels higher than allowed. These include:

1. Two alternatives manage the waste as is; in failing tanks,
2. Two alternatives leave all or most of the tank waste in the tanks covered with sand and a complex barrier to keep rain water out,
3. One alternative proposed vitrifying all of the waste in the tanks in place.

A sixth alternative was added as the EIS went to print. This alternative is included in the cover letter for the EIS and is not analyzed in depth in the EIS. It would leave most of the waste in the SSTs, fill the tanks with sand and cover them with a barrier.

Response DOE and Ecology acknowledge the preference expressed in the comment and will take this preference and other public comments into consideration when making a final decision on remediating the TWRS waste. NEPA requires an EIS address a comprehensive range of reasonable alternatives. The TWRS EIS fully addresses 10 alternatives for tank waste, which includes no action, long-term management, in situ, ex situ, and combination alternatives. NEPA also requires that these alternatives be analyzed regardless of regulatory compliance to allow an even-handed analysis of all factors, as discussed in the response to Comment number 0072.80. Please refer to the response to Comment number 0040.01 for a discussion of factors influencing the evaluation of alternatives.

Comment Number 0078.03

ODOE

Comment

Unacceptable Alternatives

The EIS includes four alternatives which meet legal requirements. These are:

1. Retrieve all of the waste, glassify it and sent it to a national high-level nuclear waste repository,
2. Retrieve all of the waste, use extensive chemical processes to separate the nonradioactive portions from the radioactive portions, glassify them and send the glass to a national high-level nuclear waste repository,
3. Retrieve all of the waste, use less extensive separations of the waste into high-activity and low-activity fractions, glassify, both, bury the low-activity fraction at Hanford and send the high-activity fraction to a national high-level waste repository (Government owned and contractor operated),

4. Do the same as three, but do it in phases using private companies to build and operate the plants. (This is the preferred alternatives in the EIS).

If privatization fails, the Tri-Party Agreement requires USDOE to revert to government owned and operated vitrification plants.

Response DOE and Ecology acknowledge the preference expressed in the comment and will take this preference and other public comments into consideration when making a final decision on remediating the TWRS waste. Please refer to the response to Comment number 0040.01 for a discussion of factors influencing the evaluation of alternatives. Please also refer to the response to Comment number 0072.80 for a discussion of the NEPA requirements to analyze a full range of alternatives in an EIS regardless of regulatory compliance.

Comment Number 0079.01

Knight, Paige

Comment Hanford Watch supports the phased implementation plan, not because it's so great, but because it gets the waste out of the tanks. It is our conviction that waste must be removed from the tanks and put in a stable form. If this new preferred alternative reaches a point of failure, you must be prepared to turn back immediately to the path outlined in the Tri-Party Agreement, and follow the advice given by the Tank Waste Task Force, in the summer and fall of 1993. That advice can be summed up in the words get on with cleanup. The public has stated time and time again that the DOE must get on with it. Hear us. Do not change paths again.

Response DOE and Ecology acknowledge the preference expressed in the comment and will take this preference and other public comments into consideration when making a final decision on remediating the TWRS waste. Please refer to the response to Comment numbers 0072.05 and 0076.03. Please also refer to the response to Comment numbers 0009.19 and 0060.02 for more information on the reasons Phased Implementation was identified as the preferred alternative.

Comment Number 0079.03

Knight, Paige

Comment The alternative of long-term management also is unacceptable because according to the TWRS EIS that document will end in, that management will end in 100 years. This possibility the amount of time previous to the waste plumes becoming a severe health risk to the public and the environment.

Response DOE and Ecology acknowledge the preference expressed in the comment and will take this preference and other public comments into consideration when making a final decision on remediating the TWRS waste. Please refer to the response to Comment number 0040.01 for a discussion of factors influencing the evaluation of alternatives. Please refer to the response to Comment number 0040.02 and 0101.01 for a discussion of the 100-year administrative control period.

Comment Number 0079.04

Knight, Paige

Comment The in situ alternative is also unreasonable, because again no protection of the groundwater is offered, and security and external control will end in 100 years. And that's when the contamination, theoretically, is going to become a real problem for the health and environment, health of people and environment. Further, the use of riprap basalt is suggested. And we fear that this material will be taken from sites at Hanford, that are sacred to the Indian tribes.

In short, any plan to leave this deadly brew of wastes in the tanks is totally unacceptable, and will meet with the resounding opposition from the citizens of the region. Water is sacred, and must be protected at all costs.

Response DOE and Ecology acknowledge the preference expressed in the comment and will take this preference and other public comments into consideration when making a final decision on remediating the TWRS waste. Please refer to the response to Comment number 0040.01 for a discussion of factors influencing the evaluation of alternatives. Please refer to the response to Comment numbers 0091.01 and 0012.01 for discussions of groundwater issues related to current and planned monitoring programs and protection of the Columbia River.

Volume One, Section 5.7 describes the land-use impacts of the various alternatives, including impacts to potential borrow sites. Volume One, Section 5.5 describes the cultural resources impacts, including prehistoric and historic sites, and issues of potential concern to Native Americans. DOE and Ecology remain committed to protecting the groundwater beneath the Hanford Site and the Columbia River and impacts to groundwater and the Columbia River are addressed in Volume One, Section 5.2 and Volume Four, Appendix F. Please see the response to Comment number 0019.03 for a discussion of borrow site issues. Please refer to the response to Comment number 0040.02 and 0101.01 for a discussion of the 100-year administrative control period. Response to Comment numbers 0091.01 and 0012.01 discuss groundwater issues related to current and planned monitoring programs and protection of the Columbia River.

Comment Number 0085.01

Klein, Robin

Comment Except to say that the no action alternatives, including long-term management are unacceptable options. They are not within the range of reasonable alternatives as the Draft EIS states. But are imprudent, hazardous, and in violation of the Tri-Party Agreement.

Response DOE and Ecology acknowledge the preference expressed in the comment and will take this preference and other public comments into consideration when making a final decision on remediating the TWRS waste. Please refer to the response to Comment number 0040.01 for a discussion of factors influencing the evaluation of alternatives. Please also refer to the response to Comment numbers 0072.52, 0072.05, 0078.02 and 0072.80.

Comment Number 0087.04

Tewksbury, Ross

Comment And I think that they should do the extensive waste retrieval and vitrify all, or nearly all of it, and whether it's stored on the site, or off the site is not really the major thing. The major thing is to get it in a form where it's not able to leak out into the groundwater and soil and the river, and everything else, and to do that as fast and as safely as possible. And I think that you should not really be concentrating on this waste separation idea that you were going over tonight, except what's absolutely necessary for the technical, chemical, and safety purposes. Because all of it has to be taken care of for hundreds, if not thousands of years. Thank you.

Response DOE and Ecology acknowledge the preference expressed in the comment and will take this preference and other public comments into consideration when making a final decision on remediating the TWRS waste. Please refer to the response to Comment numbers 0072.05 and 0078.02. The phased approach to the alternative implementation is discussed in the response to Comment numbers 0060.04 and 0076.03. Groundwater protection issues are discussed in the response to Comment numbers 0091.01 and 0012.01.

Comment Number 0088.01

Porter, Lynn

Comment I guess I support the preferred alternative because it sounds better than the others.

Response DOE and Ecology acknowledge the preference expressed in the comment and will take this preference and other public comments into consideration when making a final decision on remediating the TWRS waste. Please refer to the response to Comment numbers 0014.04, 0072.05, 0078.02, 0009.19, and 0060.02 for a discussion of the reasons Phase Implementation has been identified as the preferred alternative.

Comment Number 0089.01

Nez Perce Tribe ERWM

Comment The Nez Perce Tribe ERWM favors protection of the Columbia River and its ecosystem through removal and disposal of tank wastes from 200 Area tanks as supported by the EIS. ERWM believes groundwater and the Columbia River are at risk from potential radionuclide or toxic chemical releases from the tanks. We endorse the alternative calling for removal of tanks wastes through one of the Ex Situ Separations alternatives or Phased Implementation.

Response DOE and Ecology acknowledge the preference expressed in the comment and will take this preference and other public comments into consideration when making a final decision on remediating the TWRS waste. Please refer to the response to Comment numbers 0014.04, 0072.05, and 0078.02.

DOE and Ecology remain committed to protecting the groundwater beneath the Hanford Site and the Columbia River and its ecosystem. An analysis of impacts to groundwater and the Columbia River are provided in Volume One, Section 5.2 and Volume Four, Appendix F. Discussions related to groundwater and protection of the Columbia River are contained in the response to Comment numbers 0091.01 and 0012.01.

Comment Number 0093.02

Devoy, Tiffany

Comment I also would like to say that I do think the Tri-Party Agreement should be followed in this case and actually in most cases and it seems odd that there is always someone trying to get out of it. It was signed and I think it should be followed. I think that they need to vitrify as much waste as possible and to leave as little waste behind as possible and I do not think that is an unrealistic expectation. There are 177 tanks and I do not even remember what was quoted to me as to how many gallons each those tanks were but it is pretty amazing and to think of all that waste concentrated and to just leave it there, I know that is not your preferred alternative, but I think some of your alternatives are not that much better. So vitrify it as much as possible, leave as little behind as possible, and follow the Tri-Party Agreement. That is about it.

Response DOE and Ecology acknowledge the preference for extensive waste retrieval, treatment, and disposal within the context of the Tri-Party Agreement expressed in the comment and will take this preference and other public comments into consideration when making a final decision on remediating TWRS waste. The inclusion of alternatives in the EIS that do not comply with the Tri-Party Agreement complies with the NEPA, which is the Federal law requiring the preparation of this EIS. Please refer to the response to Comment numbers 0072.10 and 0072.80 for a discussion on requirements for inclusion of alternatives in an EIS analysis.

L.3.4.2 Elements Common to Tank Waste Alternatives

Comment Number 0098.03

Pollet, Gerald

Comment The public deserves to know how much money is going to be taken out of the authorization for Hanford clean up for the so-called privatization reserve. This process is a sham so long as an undisclosed amount of your Hanford clean up dollars are being removed in the future. Let us face it, basically the President and Congress have said you are going to have less money for Hanford clean up, we know what the President's projection is, it is seriously less than it used to be, and out of that a future chunk is going to privatization in a liability reserve but you and I can not see what it is. At the same time, the Department of Energy has target budgets now through the year 1998 which fail to fully fund essential safety and Tri-Party Agreement activities such as characterizing the wastes in these tanks. As the General Accounting Office has said, If you fail to properly characterize, you can not expect the contractors to be able to vitrify and, in fact, anyone can see down the road that the contractors are liable to say, You did not characterize properly, therefore, you owe us the full cost we put out for building the plant and our anticipated profit, we will take that 1.4 whatever billion dollar reserve it is, put it in our corporate pockets, the government will be out that money, you will have a plant that will not work because wastes were not characterized. Currently, the Department of Energy is planning in its budgets to be at least 3 years behind the Tri-Party Agreement requirement for characterizing the wastes. This can not be allowed to go forward.

Response DOE and Ecology acknowledge the preference expressed in the comment and will take this preference and other public comments into consideration when making a final decision on remediating the TWRS waste. The privatization contracting strategy and the budgetary process for funding the alternative selected are outside the scope of this EIS. DOE Richland Operations office prepares a budget each year, which includes funds required for cleanup; however, only Congress has the authority to appropriate funds. Please refer to the response to Comment numbers 0012.14 and 0072.14 for discussions of issues related to the tank waste inventory and ongoing efforts to characterize the tank waste.

Comment Number 0101.01

Yakama Indian Nation

Comment Unrealistic Assumptions Regarding Institutional Controls Restricting Future Human Actions --Design basis assumptions associated with the disposal of waste at Hanford optimistically assume protective conditions will exist in the future in connection with the estimation of impacts to the public

health and safety and the environment. Specifically, we consider the assumption of institutional controls restricting intruder actions or inadvertent intruder actions beyond about 130 years hence is invalid.

Response DOE and Ecology concur that intruder or trespasser activities could not be monitored or restricted beyond 100 years. The 100-year administrative control period is a bounding assumption used during the analysis of the alternatives. For all alternatives analyzed in the EIS, post-remediation risks assume that institutional controls would not exist beyond 100 years. Please refer to the response to Comment numbers 0040.02 and 0040.03 for more information regarding administrative controls. Because the information contained in the text was correct, no change was made to the document.

Comment Number 0101.04

Yakama Indian Nation

Comment Consideration of Low-Impact Waste Management Alternatives--Alternatives which evaluate impacts associated with the minimization of the volume of waste retaining a long-lived hazard (hazardous for 130 years or more) and large cask storage of stabilized wastes was not accomplished. We believe such options which were addressed in preliminary impact analyses, should be presented in the impact statement to allow full assessment of options. We consider that DOE (OCRWM) actions in preparation of the EIS to require consideration of small casks with no apparent technical or economic basis is unwarranted and capricious.

For example, the use of 10 cubic meter capacity (m^3) (360-cubic foot [ft^3] casks for storage and/or disposal of stabilized high-level radioactive wastes should be evaluated. Furthermore, consistent with evaluating alternatives which minimize the volume of waste for disposal, the option of using waste processes that would purify sodium salts (making up about 85% of the solids in the tanks) to a specific activity and hazard equivalent to Class A low-level radioactive waste with the calcination of the remaining high-level radioactive waste stream should also be specifically compared with processing options that produce larger volumes of long-lived hazardous wastes.

We note that the an additional benefit of removing sodium is the added stability of potential high-level radioactive waste forms without significant sodium, making this processing option desirable for disposal performance assessments.

Response The Ex Situ No Separations Vitrification and Ex Situ No Separations Calcination alternatives have been revised for the Final EIS to use a 10-m^3 (360-ft^3) canister for HLW storage and disposal. The size assumptions are presented in Volume One, Section 3.4 and Volume Two, Appendix B. These canister sizes have been used for impact analysis presented in Volume One, Section 5.0, Volume Three, Appendix D, Volume Four, Appendices E and F, and Volume Five, Appendices G and H. Please refer to the response to Comment number 0081.02 for related information.

The use of crystallization to remove sodium salts from the waste stream is included in the Ex Situ Extensive Separations alternative as a technology that could potentially reduce the LAW volume. This technology was not included as a primary treatment technology because it was not sufficiently mature to allow detailed evaluation. The focus of the EIS was to evaluate alternatives, rather than specific technologies, to allow sufficient flexibility to evaluate and implement emerging technologies in the future. Please refer to the response to Comment number 0072.05 for information on NEPA alternatives analysis requirements.

DOE and Ecology agree that removal of the sodium from the waste stream prior to immobilization potentially would reduce the volume of HLW for the Ex Situ No Separations Vitrification alternative and LAW for the ex situ alternatives that include separating the HLW and LAW for treatment. It would be expected that removal of the sodium would result in increasing the waste loading such that either waste form would meet waste form performance criteria. Please refer to the response to Comment numbers 0027.11 and 0008.01 for more information related to waste loading and the response to Comment numbers 0008.01 and 0009.08 for more information regarding consideration of canister (cask) size in the Draft and Final EIS.

Comment Number 0101.07

Yakama Indian Nation

Comment On another scale the impacts associated with the disposal of waste streams generated by the actions being considered must also be considered in a integrated manner. The issue associated with waste minimization and waste package sizing greatly affects disposal costs and other impacts, particularly those associated with the high-level radioactive waste deep repository at Yucca Mountain. Integration of the disposal facilities under the office of Civilian Waste Management (OCRWM) and the TWRS in DOE's overall environmental management actions should be evaluated and assessed from a systems engineering approach to resolve this issue.

We consider large savings (several billion dollars) are possible if valid systems integrations are accomplished compared to the base-line alternatives currently being pursued by DOE. These estimates stem from cost evaluations accomplished by the authors of the subject EIS.

Response Large canisters have been addressed in the Final EIS.

Please refer to the response to the following comments for more information:

- Comment numbers 0004.01 and 0081.02 - coordination with Office of Civilian Radioactive Waste Management (OCRWM) and revisions to repository cost calculations
- Comment number 0008.01 - canister size re-evaluation decision
- Comment number 0027.02 - systems engineering approach to the alternatives evaluation
- Comment number 0037.04 - relationship of the TWRS EIS to other Sitewide NEPA and programmatic documents.

The cost estimates in the EIS include contingency and a range of uncertainty based on the conceptual nature of the alternatives and standard industry practice for large capital projects. DOE expects that as detail design progresses, progress in technology optimization will result in cost savings. Please refer to response to Comment numbers 0052.04 and 0081.03.

L.3.4.2.1 Issues Related to Disposal Costs Calculations and Repository

5. TRW, 1995, *Assessment of Pre-Closure System Cost and Health and Safety Impacts of Hanford HLW Vitrification Options on the Civilian Radioactive Waste Management System*, A00000000-01717-5705-00003, Rev. 0, TRW Environmental Safety Systems, Inc., Vienna, Virginia, April 27, 1995.

The geologic disposal costs presented in section B.3.0.8 of the draft TWRS EIS (ref 1) are based on a linear extrapolation of the unit container disposal costs provided by reference 2 for a specific scenario. The linear extrapolation of the unit container disposal cost from reference 2 to all the TWRS alternatives does not meet the requirements of the Nuclear Waste Policy Amendments Act (ref 3) and Federal Register Notice 52-161 (ref 4).

Federal Register Notice 52-161 identifies, in detail, the method to be used in estimating the disposal fees for the Department of Energy defense program HLW (HLW) share of total Civilian Radioactive Waste Management System (CRWMS) costs. Federal Register Notice 52-161 cost allocation is based on the concept of full cost recovery with sharing formulas applied to all fixed and variable system cost components.

The assumption of linear extrapolation of unit container disposal costs in the draft TWRS EIS greatly underestimates the disposal costs of the extensive separations alternative and greatly overestimates the disposal costs of the no separations alternative. Example disposal cost variability for alternate HLW container sizes and HLW volumes resulting from no separations, intermediate separations, and extensive separations using the methodology specified in Federal Register Notice 52-161 are provided in reference 5.

I am requesting that the draft TWRS EIS be revised to incorporate HLW disposal costs calculated with the methodology specified by Federal Register Notice 52-161.

Response As stated in Volume One, Section 3.4, the repository fees are based on the 1995 Analysis of the Total System Life Cycle Cost (1995 TSLCC) of the Civilian Radioactive Waste Management Program. The Draft EIS also acknowledges that the 1995 TSLCC was based on a single scenario and one repository. It is acknowledged that there is uncertainty in identifying a disposal fee prior to the final licensing of a national repository. Additional uncertainty results from analyzing various options considered in the EIS as the number of canisters varies from the baseline. However, DOE will comply with the provisions of the Nuclear Waste Policy Act requiring full cost recovery. The purpose of the cost analysis is to provide a basis for comparison among the alternatives (TWRS Draft EIS, Volume Two, Appendix B, page B-40).

In response to public comment, for the Final EIS, DOE and Ecology have reevaluated the estimate of disposal costs presented in the Draft EIS, using the 1987 methodology to more accurately reflect possible costs associated with disposal for the various canister options presented. This effort was coordinated through the OCRWM. Please refer to the response to Comment numbers 0081.02 and 0008.01 for additional information.

Swanson, John L.

Comment I do not get the point of the sentence on page 3-37 "The use of a standard-sized canister does not consider waste loading, which ranges from 113,000 curies per canister to about 300-."

Response The use of the term "waste loading" here certainly could be confusing as it also refers to the waste loading of the glass with respect to percent sodium or waste oxides. Individual chemical entities such as sodium were considered in the "waste loading" of the glass. The quantity of radioisotopes and curie content was not limited in the glass formulations because the maximum heat load per canister was below the limit of 1,500 watts set for the repository.

The Final EIS was revised to include larger HLW canisters, which eliminates the need for the subject discussion in Volume One, Section 3.4. Please refer to the response to Comment numbers 0008.01 and 0081.02 for more information.

Comment Number 0008.01

Evett, Donald E.

Comment First, Current planning also assumes that this waste could be contained in approximately 18,000 standard-sized canisters. Also, there is insufficient capacity in the first repository to accept all Hanford Site -high-level waste under almost every alternative. Your study states that an estimated $360,000 cost per canister disposed of at the repository. The report alludes to the feasibility of using much larger canisters whereby the repository fees could be substantially reduced. In my opinion, I would think that the Department of Energy would vigorously pursue the much larger canisters.

Response Larger HLW canisters result in fewer waste packages for disposal at the geologic repository and offer substantial cost savings over the use of standard-sized HLW canisters. DOE is pursuing the use of HLW canisters that are larger than the standard-sized canister currently defined in the repository Waste Acceptance Systems Requirements Document (DOE 1994g). Since the Draft EIS was published, DOE-RW has acknowledged the technical feasibility of a larger canister for HLW and an independent technical review team convened to review the waste loading and blending assumptions used in the Draft EIS. The recommendations of the independent technical review team, along with the larger HLW canister specifications, have been incorporated into the ex situ alternatives for the Final EIS. The use of larger canisters and revised estimates for HLW volumes have been incorporated into the repository fee estimates shown in the Summary, Volume One, Section 3.0, and Volume Two, Appendix B. Section 3.4 describes the common assumptions for canister size and waste loading and additional detail is provided in Appendix B. Please refer to the response to Comment number 0081.02.

Comment Number 0008.02

Evett, Donald E.

Comment What happens if the Yucca Mountain project is defeated? What happens next and where will the canisters be disposed? If the year 2015 is the earliest date for acceptance of the high-level waste in canisters, where will the canisters be stored until this time? It is assumed that the use of canisters can commence much earlier than the year 2015.

Response DOE fully intends to comply with the Nuclear Waste Policy Act of 1982 as amended, which requires development of sites suitable for long-term disposal of spent nuclear fuel and HLW, and with DOE Order 5820.2A, which requires that HLW be processed and disposed of in a geologic repository. Therefore, disposal of HLW in a geologic repository was assumed and used as the basis for all alternatives involving HLW retrieval. The in situ and combination alternatives would result in onsite HLW disposal and the EIS analyzes the impacts associated with those actions. See Volume One, Section 6.0 for a discussion of the regulatory requirements and Volume One, Section 3.4 for assumptions associated with the geologic repository included in the EIS. Onsite storage at the Hanford Site for the HLW under the ex situ alternatives for up to 50 years is analyzed in the EIS. If longer-term storage is required due to delays in opening the geologic repository for disposal, appropriate NEPA analyses will be conducted.

Comment Number 0012.06

ODOE

Comment A large part of the cost shown for the vitrification alternatives included charges to dispose of the waste to the national high-level waste repository. These charges should not be used to decide whether to put the waste in a stable and durable form.

Several alternatives call for removal of all wastes from the tanks and vitrification. They differ in the methods used, complexity, speed and cost. The repository charges should be used as one criteria in deciding among these alternatives.

Response DOE and Ecology acknowledge the preference expressed in the comment and will take this preference and other public comments into consideration when making a final decision on remediating the TWRS waste. The cost estimates developed for each ex situ alternative presented in Volume One, Section 3.4 list the treatment cost, the estimated repository fee, and a total alternative cost range that combines treatment cost and estimated repository fee. The estimated repository fees, as acknowledged in the Draft EIS, have a high degree of uncertainty. Please refer to the response to Comment numbers 0004.01, 0008.02, and 0081.02 for more information concerning repository costs, canister size, and related uncertainties.

Comment Number 0027.02

Roecker, John H.

Comment Technical Data Manipulation

In Chapter 3 (page 3-33) DOE discusses the wide range of HLW canisters that could be produced and it makes reference to a WHC document for the low end of the range and a DOE document for the high end. The WHC document is an engineering document containing factual technical data and the DOE document is a set of comments on the TWRS System Requirement Document, which are not supported by technical data. This is another example of DOE Headquarters continuing to manipulate the technical data to support and satisfy their agenda rather than letting facts tell the story openly and honestly. Incidentally, the TWRS System Requirements Document has not yet been approved, to my knowledge, but yet here we are reviewing EIS alternatives which are supposed to be based on systems engineering. More on that later. I would request that in the Final EIS such manipulations of the technical data be eliminated and that all data be presented in accordance with standard systems engineering techniques and principles.

Response Because the alternatives evaluated in the EIS are conceptual at this time, engineering feasibility is limited to an Implementability review for each alternative. This is consistent with CEQ guidance that NEPA analysis occur as early in the decision making process as possible and always before irreversible and irretrievable commitments of resources have been made (40 CFR 1500). Following the publication of the Final EIS and approval of the TWRS ROD, a systems engineering and safety analysis of the preferred alternative will continue during the detailed design phase of the demonstration facilities. DOE intends to continue using systems engineering as a method for evaluation and implementation of the TWRS mission. It is anticipated that the detailed design of the waste retrieval, transfer, treatment, and storage demonstration facilities will be conducted using the system engineering and safety requirements currently being developed for TWRS (and concurrently with the TWRS Draft EIS).

The EIS presents an unbiased evaluation of each of the alternatives using the best available information. More information on canister assumptions and revisions to the EIS in response to revised information on canister size can be found in the response to Comment number 0008.01

Comment Number 0027.05

Roecker, John H.

Comment Repository Cost

I am not a lawyer, but in my reading of the Nuclear Waste Policy Act (NWPA) of 1982 as amended in 1987 and the Federal Register Notice 52-161 I believe it is quite clear on how the repository fee for disposal of HLW should be calculated. The use of linear extrapolation of a unit container cost for a specific disposal scenario to calculate the repository fee for all alternatives is completely wrong, misleading and totally obscures the real cost of each alternative. The use of a linear extrapolation of unit container cost greatly understates the cost of disposal for the extensive separations alternative and greatly overstates the cost for the No Separations alternative. This is a blatant example of data manipulation to make a particular alternative look attractive and misleads both the public and decision makers.

Response Please refer to the response to Comment numbers 0004.01, 0008.01, and 0081.02.

Comment Number 0027.07

Roecker, John H.

Comment Use of 0.62 m^3 HLW Canister

Requiring Hanford to use the 0.62 m^3 canister is overly restrictive and ridiculous particularly in light of the fact that a larger canister will be required for spent nuclear fuel. A larger HLW canister is a significant advantage for Hanford waste disposal and should be utilized.

Response DOE and Ecology recognize the potential benefits of using a larger canister for HLW. The use of larger HLW canisters has been included in the Final EIS. The size assumptions are presented in Volume One, Section 3.4 and Volume Two, Appendix B. These canister sizes have been used for impact analysis presented in Volume One, Section 5.0 and Appendices D, E, F, G, and H. Please also refer to the response to Comment number 0008.01 for more information on canister size and related impact on repository costs.

Comment Number 0035.04

Martin, Todd

Comment A clear stakeholder value has been that Yucca Mountain should not drive decision. We have said that the best waste form should determine which waste form is used, not the site, nor size, nor cost of a speculated national repository.

Response DOE and Ecology acknowledge the preference expressed in the comment and will take this preference and other public comments into consideration when making a final decision on remediating the TWRS waste. Repository considerations associated with the size, location, and cost of the potential repository did not drive the EIS analysis of waste form. The waste forms analyzed in the EIS are discussed relative to their ability to comply with existing waste acceptance criteria at the proposed repository; however, the analysis shows that the only waste form acceptable at the proposed repository is the one presently identified in the Tri-Party Agreement. This waste form is a borosilicate glass. Further, the information regarding timing is presented to provide a base case plan for analysis of impacts as required under NEPA. Information regarding the size of the repository is presented to inform decision makers and the public of the potential impact of TWRS waste on planning for the repository and the potential need for a second repository. In all cases, the EIS assumes, for purposes of impact analysis, that the waste would be stored on an interim basis at the Hanford Site and ultimately shipped for disposal at a geologic repository. The Final EIS has been revised to provide for up to 50 years of interim storage onsite. Each ex situ alternative includes interim onsite storage large enough to hold all HLW produced. This allows the waste treatment program to move forward with out relying on the geologic repository. The interim storage method provides for shielded storage of the immobilized HLW, protective of human health and the environment.

This is consistent with the Tank Waste Task Force value that DOE "accept the fact that interim storage, at least, of the waste in an environmentally safe form will occur for some time at Hanford" (HWTF 1993). Later in the Tank Waste Task Force report when addressing waste storage, a discussion is included that advises DOE to "assume temporary storage will occur at Hanford but don't assume that all radionuclides should be here forever." Please refer to the response to Comment numbers 0008.02, 0004.01, 0038.10, 0052.01, 0035.04, 0012.11, and 0055.03 for all issues related to tank waste disposal and the TWTF.

Comment Number 0035.05

Martin, Todd

Comment I would like to address the cost estimates and how they effect the TWRS EIS, particularly in regards to Yucca Mountain.

If you look at some of the simple technical assumptions that are made in the EIS, such as waste loading, the amount of waste that gets into the glass, it dramatically affects cost.

The waste loading has been altered by a mere factor of a little bit more than 10 percent over the last couple of months. Some of the blending assumptions have been changed.

What does that do to cost? If you look at the preferred alternative, it changes the repository cost from four billion dollars all the way up to 12 billion dollars. That is a big impact for such a small change.

The no separations options, change the canister size. What does that do to the cost? It changes the repository cost from about 13 billion all the way up to over 250 billion dollars.

These overly conservative assumptions and the uncertainty with the repository are driving the costs that we see in this EIS. That is inappropriate, and the stakeholders have made that clear in the past.

Response The repository fees presented in the Draft EIS for the ex situ alternatives were overly conservative, but consistent with the published information DOE had at the time the Draft EIS was published. The Final EIS has been modified based on new guidance from the repository and an independent technical review of the Draft EIS. Please refer to the response to Comment numbers 0004.01 (repository fees and associated uncertainty), 0008.01 (canister size assumptions and associated changes in repository costs), 0027.11 (HLW waste loading), 0035.04 (comprehensive repository issues), and 0081.02 (separation of respository costs from alternative costs).

Comment Number 0036.01

HEAL

Comment Unfortunately, the repository plays an important role in the cost analysis of EIS alternatives. The EIS does include the speculated repository cost as a separate cost item, allowing the careful reader to see the role the repository plays in cost. This is an improvement. But many will not read beyond the Summary -- where the total cost is the only number available. The EIS itself makes a very good case for removing the repository cost numbers:

(The estimate of repository disposal costs)"... is an estimate based on numerous assumptions. Nor should the assumptions used in the analysis be interpreted as final DOE policy. The program is in the early stages of development and design concepts for items such as the repository surface facility, underground layouts, and waste packages are very preliminary. The techniques used to estimate the total system cost were appropriate to the limited level of design development and entail a corresponding level of uncertainty ... There is a high degree of uncertainty in using a fixed cost per canister for geologic disposal over the wide range in the number of canisters that would be produced for the TWRS alternatives." (p. 3-37)

In other words, there is almost no basis for the repository disposal costs and they should not be trusted.

The continued high-profile role of the speculated repository is unacceptable. It goes against past stakeholder values and common sense. Further, the EIS itself says that DOE will bring the program to a safely stored state at Hanford, regardless of the repository's existence. Each of the ex situ alternatives will include onsite storage sufficient for ALL the waste. According to the EIS, "This would allow each of the alternatives to operate independent of the acceptance schedule for the potential geologic repository" (p. 3-38). The Final EIS must be rewritten in such a way as to clearly put the repository in perspective and dramatically reduce the role the repository plays in the document.

Response DOE and Ecology acknowledge the preference expressed in the comment and will take this preference and

other public comments into consideration when making a final decision on remediating the TWRS waste. The Final EIS has been revised to discuss HLW disposal at the geologic repository

and the associated cost separately. See Volume One, Section 3.7 and Volume Two, Section B.9 for the revised discussion of HLW disposal at the geologic repository. Please refer to the response to Comment numbers 0004.01, 0008.02, 0035.04, and 0081.02.

Comment Number 0036.02

HEAL

Comment The EIS is biased to maximize the cost impact of the national repository.

Over the last few months, changes in waste loading, blending, and canister assumptions have maximized repository costs. The assumption changes are a radical departure from past TWRS assumptions and are not based on any evident engineering data.

Assuming waste loadings similar to those in Tri-Party Agreement studies results in the following repository fees:

- about $4 billion dollars for the "Phased Implementation" alternative.
- about $13 billion for the "no separations" alternative.

After the assumptions were changed, the "Phased Implementation" repository fee rose to about $12 billion and the "no separations" skyrocketed to over $250 billion. Meanwhile, the repository fee for extensive separations stayed relatively constant.

These assumptions may seem minor, but obviously have a large -- and inappropriate -- impact.

Response DOE and Ecology acknowledge that the repository fees presented in the Draft EIS for the ex situ alternatives were overly conservative. The data to support the TWRS EIS assumptions, analysis, and calculations were cited in the Draft EIS and engineering data packages, and calculations were provided for public review in DOE Reading Rooms and Information Repositories. The Final EIS has been modified based on new guidance from the repository and an independent review of the Draft EIS. Please refer to the response to Comment numbers 0004.01, 0008.02, 0035.04, and 0081.02.

Comment Number 0037.03

Eldredge, Maureen

Comment I am concerned about the cost estimates in the program, particularly including repository costs. It does not make any sense. It is ludicrous. We do not have a repository. DOE needs to wake up to that fact.

We are not going to get a repository any time soon, not by 2015. It is just not going to happen. We do not know what the repository, if we ever get one, will look like. We do not know what its loading requirements will be. We do not know what its technical capabilities will be. We do not know what its size will be.

Any predictions of cost for a repository are highly speculative. Even if Yucca Mountain by some chance happened to open in any kind of reasonable time frame, the first people in line are the commercial nuclear utilities.

And believe me, they are going to make sure they keep their place first in line. And they are going to make sure all of their waste gets into the facility before any defense waste gets a chance.

Even if defense waste gets in the door, only 10 percent of the repository is slated to be for defense high-level waste. And I am afraid that we are going to run out of space at Yucca Mountain at least very soon, if it opens at all.

Then we are looking at a really fun option of going for a second repository. It is just not going to happen. And it is time to start making plans and start looking at the future with more reasonable expectations.

Response The siting, design, and licensing of a geologic repository to isolate spent nuclear fuel and HLW for long-term protection of public health and safety of the environment is a highly technical and complex process. As stated in Volume One, Section 6.2, the current program planning assumption is that any DOE material qualified and selected for emplacement in the first repository would be disposed of beginning in the year 2015.

As stated in the EIS, current national policy calls for the disposal of spent nuclear fuel and HLW in a geologic repository. The ex situ alternatives presented in the TWRS EIS were developed to be consistent with this policy. Current projections for commercial spent nuclear fuel and defense HLW exceed the statutory limit of 70,000 equivalent metric ton heavy metal (MTHM) in the first repository. The need for a second repository will not be addressed until between January 1, 2007 and January 1, 2010 when the Secretary of Energy is required to report to the President and Congress under the Nuclear Waste Policy Act. Please refer to the response to Comment numbers 0004.01, 0008.02, 0012.20, 0035.04, and 0069.04 for additional information.

Comment Number 0038.10

Reeves, Merilyn

Comment The cost of the national repository, which you have heard about tonight, it should be removed from the EIS. The hypothetical, national repository has been a driver for the tank waste treatment and disposal decisions. And this is not in the best interest of cleanup at Hanford.

The Tank Waste Task Force of 1993 was very clear, quote, let the ultimate best form for the waste drive decisions, not the size, nor the timing of the national repository.

The repository costs are not broken out in the summary, misleading the reader by not communicating the importance of repository costs for each option. And the speculated cost of repository should be removed from the EIS.

Response The presentation of the cost estimates has been revised for the Final EIS by separating the cost and discussion regarding HLW disposal. See Volume One, Section 3.7 and Volume Two, Section B.9 for HLW disposal costs. There are real costs associated with disposal of HLW at the geologic repository, and removal of these cost estimates from the EIS would not allow for an equitable comparison among the alternatives as required under the NEPA process. It is necessary to show these costs in the EIS to fully inform the public and the decision makers of the total cost of the alternatives. Please refer to the response to Comment numbers 0004.01, 0008.01, 0035.04, 0052.01, 0069.04 and 0081.02 for additional information on issues related to cost estimates, the geologic repository, waste loading and waste forms, and interim onsite storage.

Comment Number 0050.01

Boldt, A.L.

Comment I have a comment on the Draft EIS disposal cost. The geologic disposal cost presented in the Draft EIS are based on the linear extrapolation of the average container disposal cost provided by the document from DORW0479 referenced in the EIS, Analysis of Total System Life Cycle Cost of the Civilian Radioactive Waste Management Program. This analysis cost in this document was for a specific scenario of waste in a number of canisters. The linear extrapolation of this average container cost - disposal cost from this previous reference to all the TWRS alternatives does not meet the requirements of the Nuclear Waste Policy Amendments Act of 1987 and the Federal Register Notice 52161, the Civilian Radioactive Waste Management Calculating Nuclear Waste Disposal Fees for the Department of Energy Defense Program Waste.

Federal Register Notice 52161 identifies, in detail, the method to be used in estimating the disposal fees for the Department of Energy Defense Program HLW share of the Civilian Radioactive Waste Management System costs. The Federal Register Notice 52161 cost allocation is based on the concept of full cost recovery with sharing formula supplied to all fixed and variable cost system or system cost components. The assumption of the linear extrapolation of average container disposal cost in the Draft EIS, greatly under estimates the disposal cost for the Extensive Separations alternative and greatly over estimates the disposal cost of the No Separations alternative. Example, disposal cost variability for alternate HLW container sizes and high-level waste volumes resulting from No Separations, intermediate separations, and extensive separations using the methodology of the Federal Register Notice 52161 are provided in a document by TRW for Environmental Safety Systems and it has long numbers on the copy I will give you but it is assessed on the pre-closure system cost health and safety in facts of Hanford high-level vitrification options on the civilian radioactive waste management system. This document is dated April 27, 1995.

I am requesting with the Draft TWRS EIS be revised to incorporate high-level waste disposal costs calculated with methodology specified in Federal Register Notice 52161.

Response Please refer to the response to Comment numbers 0004.01 (repository costs related to canisters) and 0081.02 (separation of repository, retrieval, and treatment costs).

Comment Number 0052.02

Pollet, Gerald

Comment What we need to remove from your total cost estimates is the entire set of repository fees. It is not sufficient to say that we broke out the repository fee in the details because you are still presenting a total range of cost estimates that the public and media and the decision makers are actually going to look at and they're going to say by gosh, that No Separations alternative costs a quarter trillion dollars. What kind of lunatic wanted No Separations? And what the decision makers, public, and media will not know is that, in fact, No Separation alternative actually has a rather reasonable price tag of below 30 billion dollars and that 211 billion dollars is a hypothetical repository fee for a hypothetical repository. A fee charged by the department to itself for repository which it admits in the EIS will never have the capacity for this. So it is a hypothetical fee for a hypothetical repository that the one certainty is does not have the capacity for it ever opened. There is something wrong with that picture and presenting it to decision makers, the public, and the media, it is apparent to the casual observer that someone is trying to skew the results.

Response DOE and Ecology have revised the Final EIS in response to public comment and put the costs of the repository into a separate presentation. The estimated costs for disposal of the HLW at the potential geologic repository are included in the Final EIS because there would be real costs associated with packaging, transport, and placement of HLW in a geologic repository. Eliminating the repository fees from the cost estimates presented in the EIS would not provide all of the costs associated with the alternatives and would bias presentation of the alternatives. Please refer to the response to Comment numbers 0038.10 and 0081.02 for discussion of repository costs as these issues relate to the alternatives analysis and the response to Comment numbers 0037.03 and 0008.02 for a discussion of the proposed geologic repository availability and statutory capacity.

Comment Number 0052.05

Pollet, Gerald

Comment One last closing thought for our comments tonight which is if you have a hypothetical repository fee for the hypothetical space at a hypothetical repository and the hypothetical land, then for the very real cost to the three tribes to the future generations of this region why isn't there assigned a cost for the permanent use of land in the leave it in place alternatives that are clearly being shown a preference through out all the cost estimates in this EIS. You need to consider internalizing the externalities and I would say that is less hypothetical and I think that the public could provide you and the tribes some very real cost estimates for creating a sacrifice found under the leave it there scenarios.

Response The cost estimates for the in situ or ex situ alternatives do not include cost associated with permanent land commitment, or land use restrictions associated with groundwater contamination. The amount of land committed to waste management and disposal was estimated for each of the alternatives, as was the extent of a groundwater contamination and associated human health impacts. The costs associated with long-term loss of land use or groundwater use can be understood within the overall context of the relative difference among various alternatives land use and groundwater use restrictions. The more land or groundwater is restricted the higher the cost. So while absolute dollar estimates are not provided the EIS does provide an appropriate level of analysis to support the comparison of alternatives. Land use issues related to Tribal Nation concerns are described in Volume One, Sections 5.5 and 5.19. Please also refer to the response to Comment numbers 0072.26, 0072.22, and 0036.18.

Comment Number 0055.04

Martin, Todd

Comment A third point would be that the repository should not be driving decision making at Hanford.

Response DOE and Ecology acknowledge the concern expressed in the comment. NEPA requires that all reasonable alternatives be evaluated. Consideration of geologic repository availability was included in the evaluation of the ex situ treatment alternatives in the EIS to the extent that availability was assumed; a limit would be placed on the accepted volume, type, and final waste form of Hanford materials, and the interim storage facilities would include a 50-year design life to provide sufficient time for availability. Data that support the impact analysis of each alternative are presented in an objective and unbiased format for comparison by the decision makers and the public during the comment period. Please refer to the response to Comment numbers 0008.02, 0035.04, 0037.03, 0038.10, and 0052.01.

Comment Number 0055.05

Martin, Todd

Comment I want to address cost estimates in Yucca Mountain. I think people have heard that several times but I want to address some of the specifics. In looking at the numbers, you change a few assumptions here and there and it is amazing what it does to those cost numbers. For example in Phased Implementation when we look at the repository cost. You shift the waste loading, the amount of waste that goes into the glass by a mere 10 percent into essentially a percentage that is much lower than I have ever seen in any documents. What does that do to the repository cost for that option. Moves from 4 billion dollars to 12 billions dollars. Just a little assumption like that. Let us look at the no separation option. You take a fairly large canister, your repository cost is about 13 billion dollars. Shrink that canister down a bit and it jumps to 252 billion dollars. These are the kind of assumptions that I think that Mr. Pollet pointed out appeared to have been skewed to maximum the impact of the Yucca Mountain on the EIS. And I would agree with that assertion.

Response The changes in repository cost were a result of changes to the waste loading, HLW canister size, and use of a blending factor to account for uncertainties in the ability of the retrieval operations to deliver a uniformly blended waste feed stream to the treatment facilities. The variation in estimated repository cost based on waste loading and canister size is included in the cost ranges presented in the EIS. Please refer to the response to Comment numbers 0035.04. 0038.10, and 0081.02.

Comment Number 0057.04

Garfield, John

Comment The logic of the repository cost for example in the intermediate separations adding up to $12 billion dollars does not make sense from even the simplest technical that any member of the public can understand. The Hanford contribution to the repository in total is about 1 percent of the total radionuclides if all the high-level wastes goes to the repository and about 1 percent of the heat. Whether or not content into the small number of canisters or leave it in a large number of canisters will not significantly drive the repository costs. That is a fairly straight forward and simple approach or way of thinking about that problem that everyone can understand. Attributing $12 billion dollars to that repository or $211 billion dollars for the No Separations case does not stand up to the simplest scrutiny.

Response The amount of HLW that ultimately could be accepted at a national repository is a function of available subsurface area and emplacement constraints among HLW and spent nuclear fuel (SNF) within this area. In addition, there is a statutory limit on emplacement of HLW and SNF in a first repository (70,000 MTHM) until a second repository is in operations. As a planning basis, the Department has allocated 10 percent of that statutory capacity of the first repository for defense SNF and HLW.

The physical amount of available subsurface area for HLW and SNF disposal, and the associated number of packages of HLW and SNF, would be defined through repository design and performance assessment activities, based on information collected during repository scientific investigations. Neither of these activities are completed. However, for planning purposes, the repository Advanced Conceptual Design assumes that 12,900 canisters of defense HLW, each containing 0.5 MTHM, can be accommodated within the statutory limit.

A number of factors are important in estimating disposal costs including number and size of canisters handled, number of waste packages, operation and capital costs, and number of shipments to a repository. In addition, there are common costs that must be allocated among waste generators, such as development and evaluation costs, to ensure full cost recovery. Using radionuclide inventory of Hanford HLW relative to other wastes would not provide an equitable basis for cost estimating. For more information on this issue, refer to the response to Comment number 0005.08.

A number of factors go into the repository cost estimate including heat load, canister size, waste package design, and number of waste packages. Looking at Hanford contribution of the repository cost solely from the standpoint of radionuclide contribution to the repository would not provide a straightforward and understandable basis for cost estimating. Please refer to the response to Comment numbers 0004.01, 0008.01, and 0081.02 for additional information on repository cost estimates.

Comment Number 0062.05

Longmeyer, Richard

Comment One of the things that would need to be re-looked at is if the Yucca Mountain facility is not going to become a reality, how would that affect the prioritization of these different plans. And my guess is that the Yucca Mountain facility, or any national repository for nuclear wastes, will never receive any nuclear wastes from across state lines in my lifetime, and probably not in the lifetime of my children. And so that means that we need to re-look at this, and prioritize them again. Doing so would probably leave us with three options. The in situ vitrification, the ex situ vitrification with onsite storage, and the Phased Implementation, which you have now with onsite storage. And so, those would be the three that I would recommend we look at more closely.

Response Current national policy calls for disposal of spent nuclear fuel and HLW in a geologic repository. DOE and Ecology developed the ex situ alternatives in accordance with this policy. In response to concerns regarding the timing and availability of the geologic repository to accept HLW from the Hanford Site, the Final EIS has been revised in Volume One, Section 3.4 and Volume Two, Appendix B to include the impacts associated with onsite interim storage of treated HLW for 50 years. The environmental impacts associated with the in situ alternatives identified in the comment are provided in the EIS in Volume One, Section 5.0 and associated appendices. Volume One, Section 5.12, and Volume Three, Appendix D contain discussions of the transportation risk associated with offsite disposal. Please refer to the response to Comment numbers 0008.02 (repository availability and related uncertainties) and 0037.03 (statutory limits), and 0052.01 (interim HLW onsite storage) for more information.

Comment Number 0072.84

CTUIR

Comment P3-28: PP 5: Does this mean you are only going to use one multi-purpose canister? Please explain in more detail in order for the readers to grasp how many and how much.

Response One type of multi-purpose canister was assumed as an overpack used for handling and interim onsite storage. This multi-purpose canister is referred to as a Hanford Multi-Purpose Canister (HMPC) throughout the document. The text has been revised in Volume One, Section 3.4 to discuss the relationship between the primary HLW canisters and the HMPC.

Comment Number 0077.05

ODOE

Comment A large part of the cost shown for the vitrification alternatives included charges to dispose of the waste to the national high-level waste repository. These charges should not be used to decide whether to put the waste in a stable and durable form.

Several alternatives call for removal of all wastes from the tanks and vitrification. They differ in the methods used, complexity, speed, and cost. The repository charges should be used as one criteria in deciding among these alternatives.

Response DOE and Ecology acknowledge the preference expressed in the comment and will take this preference and other public comments into consideration when making a final decision on remediating the TWRS waste. Please refer to the response to Comment number 0040.01 for a discussion of factors influencing the evaluation of alternatives. Please also refer to the response to Comment numbers 0004.01, 0035.04, 0052.01, and 0081.02 for more information regarding disposal costs, assumptions, and presentation in the Final EIS.

Comment Number 0079.05

Knight, Paige

Comment Repository costs must not be included in the total cost of any plan implemented. Cleanup dollars must go first towards stabilizing waste in a quality form that is not water soluble. Repository room must be considered. If Yucca Mountain is ever a viable option, it will only hold a small portion of Hanford waste. So the form of the waste must be not only stable, but retrievable. My reasoning there is that more than likely the waste in any kind of form is going to be sitting at Hanford for at least 40 years, and I would suspect much more than that.

Response DOE and Ecology acknowledge the preference expressed in the comment and will take this preference and other public comments into consideration when making a final decision on remediating the TWRS waste. Please refer to the response to Comment numbers 0008.01, 0038.10, and 0081.02.

Comment Number 0081.05

Pollet, Gerald

Comment More importantly is the next bullet in our advice. Accept the fact that interim storage at least, at least, of the waste in an environmentally safe form will occur for some time at Hanford. Select a waste form that will ensure safe interim storage of this waste. The message was, Hanford is going to be the home for the high-level nuclear waste. Select the best form, and don't even put into the mix the theoretical cost of the repository, which the Department will charge itself, nor the theoretical capacity of it, because it doesn't have the capacity to handle it anyway, under any scenario here. We request that this advice be addressed, and placed in the front of this EIS. And it be addressed in the summary and throughout. We request that the repository costs be relegated to an appendix, and the total cost summaries be redone to show the total cost without the theoretical hypothetical self-dealing charge for replacing waste in the repository. When that is done, we should examine carefully the no separation versus the extensive separation scenarios. And we should see how much we pay for unproven technology under extensive separation, versus no separation and intermediate separation.

Response The storage of the HLW at the Hanford Site for 50 years has been included in the ex situ alternatives. Please refer to the response to Comment number 0089.18. Current national policy calls for the disposal of spent nuclear fuel and HLW in a geologic repository and the ex situ alternatives were developed to be consistent with this policy. DOE and Ecology have revised the presentation of the cost estimates for HLW disposal for the Final EIS in Volume One, Section 3.4 and Volume Two, Appendix B. This will allow the reader to readily compare the estimated cost for waste treatment among the alternatives. There are real costs associated with packaging, transport, and placement of canistered HLW into a geologic repository, and failure of the EIS to present these costs would provide an incomplete picture for the decision makers and public. Please refer to the response to Comment numbers 0004.01, 0035.04, 0038.10, and 0069.04.

The EIS presents in Volume One, Section 3.4 and Volume Two, Appendix B, alternatives that are based on 99 percent retrieval with no separations (the Ex Situ No Separations alternative), intermediate separations (the Ex Situ Intermediate Separations alternative), and extensive separations (the Ex Situ Extensive Separations alternative). A summary comparison of these alternatives is provided in the Summary and a summary of the environmental impacts of each alternative is presented in Volume One, Section 5.14.

Comment Number 0089.18

Nez Perce Tribe ERWM

Comment Since the possibility exists that Yucca Mountain repository may not open, the design life of the onsite facility storing the vitrified high-level waste must be sufficient for the permitting and construction of an alternate high-level waste repository.

Response DOE and Ecology acknowledge the preference expressed in the comment and will take this preference and other public comments into consideration when making a final decision on remediating the TWRS waste. Volume One, Section 3.4, the Summary, and Volume Two, Appendix B.3 have been revised to include reference to the 50-year design life for the interim HLW storage facilities, which is based on a conservative estimate for approval and availability of the geologic repository. Please refer to the response to Comment numbers 0008.02, 0035.04, and 0052.11.

L.3.4.2.2 Alternatives Costs

Comment Number 0005.12

Swanson, John L.

Comment I applaud you for giving cost RANGES in comparing the different alternatives, but I am very surprised that you did not include the (large) uncertainties in HLW repository disposal costs in many of these ranges. In recent years, there have been reports of attainable cost savings through the use of higher waste loadings in HLW glass and the use of larger canisters; such savings could give estimated repository disposal costs only one-fourth as large as the values you give.

Response DOE and Ecology considered HLW disposal fees in the total cost range (treatment cost + repository fee) for the ex situ alternatives presented in the EIS. For example, when comparing the treatment cost range to the total cost range, the total cost range is not the sum of the treatment cost range and the repository fee. This methodology addressed only TWRS-specific parameters, mainly waste loading and canister size, in the cost uncertainty analysis. Uncertainties in the repository program are not within the scope of the EIS. However, 50 years of storage of the HLW is included in the ex situ alternatives to account for the uncertainty of when a repository may be available to accept waste for disposal. Please refer to the response to Comment numbers 0081.02, 0072.80, and 0008.01 for further discussions of repository and canister issues.

Comment Number 0005.13

Swanson, John L.

Comment Because of the large uncertainty in HLW repository disposal costs, I feel that it would be a more fair comparison of the costs of the alternatives in the Summary if you split out those estimates-something like "The cost of this alternative, exclusive of the HLW repository fee, is estimated to be in the range of ___ to ___. Based on the assumptions adopted for this EIS, the HLW repository fee for this alternative is estimated to be __; the use of other assumptions regarding higher waste loading in glass and the use of larger canisters could lower this estimated fee to ___."

Response DOE and Ecology recognize the concern regarding the cost uncertainty associated with the repository. The Final EIS has been revised to discuss HLW disposal at the geologic repository, the associated cost separately, and potential impacts (e.g., accidents during transportation). The Summary, Section S.8, Volume One, Sections 3.7 and 6.0, and Volume Two, Section B.9 contain a discussion of HLW disposal at the geologic repository. Please also refer to the response to Comment numbers 0081.02, 0008.01 and 0005.12 for further information regarding repository availability, cost estimate methodology, and assumptions.

Comment Number 0005.14

Swanson, John L.

Comment The more I look into your cost ranges, the more confused I become. For example; a) Footnote (3) to Table S.7.6 says that the relatively large ranges in costs for three of the alternatives is primarily a result of assumptions made for repository fee, but two of the three alternatives identified in this footnote do not fit this situation. b) Tables 3.4.13 and 3.4.14 contain footnotes indicating that the cost ranges are dependent on the canister size used, but the tables themselves give only individual values for the repository fees. Why aren't the repository fee ranges used given in the tables? Also, if the cost ranges resulting from canister size increase are given for this/these alternative(s), why aren't they given for the other alternatives as well? The way you have it is a mixture of "apples and oranges." c) Section B.8.3 ("Cost Uncertainty") does not do anything to help me, either-except to emphasize that "assumptions drive conclusions."

Response The footnote in question (footnote number 3 of Table S.7.6) is intended to provide the reader a summary-level explanation of why the cost ranges vary widely for the ex situ alternatives. The difference between the high and low cost range for the Ex Situ No Separations (Vitrification) alternative is $184 billion, the range for the Ex Situ No Separations (Calcination) alternative is $47 billion, and the range for Ex Situ Intermediate Separations and Phased Implementation alternatives is approximately $10 billion. The ranges estimated for these alternatives are greater than the other alternatives mainly because of repository fee assumptions. Technical assumptions regarding the HLW canister sizing have been revised for the Final EIS, which reduce the large cost ranges associated with the ex situ alternatives that produce large volumes of HLW. Additional detail on how the cost uncertainty and ranges were estimated is provided in Volume Two, Appendix B. Please refer to the responses to Comment numbers 0081.02 and 0005.03 for more information on uncertainty.

The Volume Two, Appendix B discussion on cost uncertainty is intended to provide an overview of the methodology and the analysis results. The detail input output data are included in the technical backup data that is publicly available as part of the TWRS EIS Administrative Record.

As noted in the response to Comment number 0005.12, the uncertainty in HLW disposal fees that would result from a variation in the number of HLW packages is included in the total cost range for each ex situ alternative. This allows for an equitable comparison among alternatives.

Comment Number 0052.03

Pollet, Gerald

Comment The costs have some other strange anomalies. For instance, some of the cost estimates for vitrification alternatives today are basable upon some market considerations in terms of what vendors are saying they believe they will be able to bid.

Response None of the cost estimates for the alternatives presented in the Draft EIS were based on privatization of the tank waste treatment. Privatization is an implementation strategy and as such was not addressed in the EIS. For a discussion of this, see Volume One, Section 3.3. All of the cost estimates were developed using the same methodology to provide an equitable comparison among the alternatives. Privatization issues are discussed in the response to Comment number 0060.01.

Comment Number 0052.04

Pollet, Gerald

Comment But what is kind of incredible in this EIS is continuing the historic practice at this site of having a capital contingency built into all the cost estimates of not just 30 percent here but 30 to 50 percent. It is really hard to talk about how the TWRS program is reaming in its costs when its capital cost estimates have a contingency added in of 30 to 50 percent. It is very disturbing and from point of view of how this is then presented to Congress, what we have is a set of alternatives that may emerge that are the ones that are necessary to meet the legal requirements of removal, retrieval, and treatment which are inflated because of their capital considerations by 50 percent and which are inflated by up to $211 billion dollars by a hypothetical repository fee and then we wonder why Congress may not want to fund vitrification.

Response The use of contingencies in cost estimates is standard practice throughout the public and private sector. This is especially true of conceptual estimates for any large construction projects. The use of a contingency in the capital cost estimates is a means to quantify the uncertainty inherent with conceptual designs. The use of contingencies is appropriate for all construction projects, especially projects involving the complexity of the TWRS program. Cost estimates associated with the repository are provided in response to Comment numbers 0004.01 and 0081.02. Capital construction costs are discussed in the response to Comment numbers 0055.06 and 0081.03. DOE-Richland Operations Office (DOE-RL) prepares an annual budget, which would include the budget required for the TWRS cleanup for that year. However, only Congress has the authority to appropriate funds.

Comment Number 0055.06

Martin, Todd

Comment On the costs more generally, I trust the costs in this document about as far as I can throw this document which needless to say without doubt is not very far. Most of the people in this room remember the Hanford Waste Vitrification Plant. This was a 1-ton a day high-level waste vitrification facility. This was the cornerstone of Hanford cleanup that as I recall is supposed to be running in about 3 years but we canceled the program. That was projected to cost about 1.3 billion dollars. Pretty hefty. I look at this EIS and I see that a low-level waste facility (vitrification facility) it is 20 mt per day. Twenty times the throughput is going to be built for 248 million dollars. I do not get it. I do not see the basis for those costs and I simply do not buy it. Further, to compare more of an apples to apples, we look at the high-level waste vitrification facility that is in the EIS. This a 1 metric ton a day facility, it is essentially HWVP. The 1.3 billion dollar facility. What is it in this EIS? 232 million dollars. I can not imagine that it can be built for that. In other words, total for the Phased Implementation alternative, DOE is going to built two low-level waste vitrification facilities with an agent pre-treatment on both of those and one high-level waste facility for 1.4 billion dollars. Essentially the cost of HWVP. I say no way. If that is true, why are we doing privatization? We can take the budget authority that has been given about 2 years and we have got the full cost of one of these facilities. This does not assume any efficiencies from privatization. These are government-owned, contractor-operated facilities, built under a traditional contracting mechanism. Essentially, until a formal credible data package has been done to support the Phased Implementation, the preferred alternative in this EIS, this EIS should go forward no further. Should go no further.

Response DOE and Ecology acknowledge this concern regarding the cost estimates and have reviewed and revised the Phased Implementation cost estimate as appropriate for the Final EIS. These revised cost estimates are shown in Volume One, Section 3.4 and Volume Two, Appendix B and are reflected in the Summary. The Hanford Waste Vitrification Plant (HWVP) cost estimate is not directly comparable to the capital cost estimate for the Phase 1 HLW facility because it includes support facilities and infrastructure that are estimated as separate components for Phased Implementation.

The Phased Implementation alternative was developed by scaling appropriate components from the Ex Situ Intermediate and Extensive Separations alternative. The capital cost was estimated using the "six-tenths rule" and the relative plant capacities for Phased Implementation were estimated in the absence of more definitive data. DOE and Ecology acknowledge that there is uncertainty introduced into the cost estimates by scaling and this is captured in the cost uncertainty analysis. The cost uncertainty analysis results in a cost range within which the final cost would be expected to fall. Total capacity cost breakdowns for a combined separations LAW facility and a detached HLW treatment facility are generally 35 percent equipment, 20 percent material, and 45 percent labor (WHC 1995j).

The cost estimates input data, methodology, and calculations are available in the reference documents included in the EIS and available for public review in DOE Reading Rooms and Information Repositories.

Comment Number 0057.06

Garfield, John

Comment There are a few other less important comments that I will make. One is with regard to the cost estimates for the combination case and to some degree the Phased Implementation case. Parsons has used 6/10ths power rule to arrive at those costs for lack of any conceptual design basis to make those estimates. That rule is applicable in the commercial industry for chemical processes because those plants are largely equipment-driven. 50 to 85 percent of those plant costs are equipment and when you vary the capacity that the capital cost of the facility does, as a rule, from varied by the 6/10ths power rule. Nuclear facility equipment costs only amounts to 10 to 20 percent of the total capital cost. That same 6/10ths power rule can not be used for a shielded nuclear processing facility. It makes no sense to do that and the cost have been skewed for using that. That adjustment should be made and can be made fairly easily.

Response The Phased Implementation alternative and combination alternatives were developed by scaling appropriate components from the Ex Situ Intermediate Separations and Ex Situ Extensive Separations alternatives. The capital cost was estimated using the "six-tenths rule" and the relative plant capacities for the Phased Implementation alternative in the absence of more substantive data. Some uncertainty is introduced into the cost estimates by scaling and this is captured in the cost uncertainty analysis presented in Volume Two, Appendix B. The cost uncertainty analysis results in a cost range within which the final cost would be expected to fall. Total capital cost breakdowns for a combined separations LAW facility and a detached HLW treatment facility estimated for the Ex Situ Intermediate Separations alternative are 35 percent equipment, 20 percent material, and 45 percent labor (WHC 1995j).

The cost estimating methodology has been reviewed and revised cost estimates have been completed for the Phased Implementation and combination alternatives, and for other alternatives as appropriate. These revised costs are shown in Volume One, Section 3.4 and in Volume Two, Appendix B.

Comment Number 0069.04

Pollet, Gerald

Comment The TWRS EIS skews the costs of the alternatives as well. This, coupled with the risks, presents a very biased picture in the EIS of the alternatives. First off, you see this is how their rank ordered in the EIS, as it will be presented to decision makers, and is being presented to you, the public. Leaving waste behind has a cost range of 23 to 28 billion. Extensive separation comes in close behind it, 27 to 36 billion. This is the Tri-Party Agreement path, called Phased Implementation, 32 to 42 billion, building just one plant basically with multiple melters, and calling it all high-level waste, glassifying it all, this astonishingly high price tag. Anyone rational would throw it out.

The repository fee, once it's removed ... excuse me, what I was saying was, the Nuclear Waste Policy Act does, indeed say how you should calculate a repository fee if your going to use it here.

It is not the way it is calculated here. Secondly, it should not be used at all because this waste will never fit into the proposed hypothetical repository at Yucca Mountain. So what is the fee for? It's a hypothetical fee the Department charges itself for a hypothetical repository that will not have room.

So all of a sudden, we have a drastic change in the order of the alternatives. In fact, what we get is, let me just present the conclusion, the Ex Situ/In Situ Combination goes from being least cost by 4 to 8 billion, to only being 1 to 7 billion dollar lower cost then getting all the waste out of there. The Extensive Separations goes from number 2 to number 4 and number 5. It goes from having a cost advantage of 5 to 6 billion dollars over the Tri-Party Agreement, to having a

5.4 to 6.4 billion dollar disadvantage over the Tri-Party Agreement path. It is an effort to skew the data here, and present it in a skew manner to decision makers. And the No Separations alternative, which gets wastes out of tanks fastest, with least research and development, actually shows up as having potentially the lowest range costs. Thank you.

Response The Phased Implementation alternative involves building two separations and LAW treatment facilities and one HLW vitrification facility during Phase 1 to demonstrate the treatment technologies. Following Phase 1, Phase 2 would be implemented, which would involve building full-scale treatment plants to treat the remainder of the tank waste. For a description of the Phased Implementation alternative, please refer to Volume One, Section 3.4.

The purpose of the Nuclear Waste Policy Act is to: 1) establish a schedule for the siting, construction, and operation of repositories that will provide a reasonable assurance that the public and the environment will be adequately protected from the hazards posed by high-level radioactive waste and such spent nuclear fuel as may be disposed of in a repository; 2) establish the Federal responsibility, and a definite Federal policy, for the disposal of such waste and spent fuel; 3) define the relationship between the Federal Government, State and affected Indian Tribal governments with respect to the disposal of such waste and spent fuel; and 4) establish a Nuclear Waste Fund, composed of payment made by the generators and owners of such waste and spent fuel, that will ensure that the costs of carrying out activities related to the disposal of such waste and spent fuel will be borne by the persons responsible for generating such waste and spent fuel. The Nuclear Waste Policy Act does not provide a methodology for calculating the repository fee for disposal of HLW in a geologic repository. For the Final EIS, repository fees were recalculated. For more information, please refer to the response to Comment numbers 0004.01 and 0036.01.

Current national policy calls for the disposal of spent nuclear fuel and HLW in a geologic repository. The current inventory of commercial spent nuclear fuel and defense HLW exceeds the statutory limit for the first repository. The disposal of all commercial spent nuclear fuel and defense HLW will require increasing the limit of the first repository or constructing a second repository. DOE is currently characterizing one site, Yucca Mountain, Nevada, for a geologic repository. The law requires that the Secretary of Energy report to the President on or after January 1, 2007, but not later than, January 1, 2010, on the need for a second repository. Within this context, none of the alternatives addressed in the TWRS Draft EIS exceed the capacity for geologic disposal, even though many of the alternatives would generate more canisters of HLW than the repository program is currently using for planning purposes. Based on revised canister size and other recalculations completed for the Final EIS, the EIS has been revised in Volume One, Sections 3.4 and 6.0, and Volume Two, Appendix B, to address the repository capacity issue relative to TWRS alternatives.

Failure to recognize that each of the ex situ alternatives would have cost impacts associated with HLW disposal would provide unequal information for the reader. Please see the response to Comment numbers 0081.01, 0081.02, and 0035.04.

Comment Number 0072.92

CTUIR

Comment P 3-36: PP 4: S 2: By what factor? Or by a factor of what?

Response Capital cost contingencies were included in the alternative cost estimates as described in Volume One, Section 3.4 and Volume Two, Appendix B. These contingencies are included to account for the uncertainty associated with the conceptual-level designs developed for analysis in the TWRS EIS. The contingency factors used ranged from 25 to 50 percent with a typical value of 40 percent. The higher contingencies were applied to the more conceptual facilities and the lower contingencies were applied to the more defined facilities. This is consistent with industry standards and practice. Please refer to the response to Comment numbers 0052.04, 0055.06, and 0057.06 for related information on the use of contingencies in cost estimating.

Comment Number 0072.93

CTUIR

Comment P 3-36: PP 6: Please explain how the R&D cost is to be assumed for the phased alternative.

Response Because Phase 1 would be a demonstration process, the research and development cost for the treatment process was assumed to be an integral part of the Phase 1 operating cost. The research and development cost associated with the waste retrieval and transfer function was included at the same level as the other ex situ alternatives. There are development programs currently ongoing at the Hanford Site that are covered under the TWRS program or other programs.

Comment Number 0077.04

ODOE

Comment Also, the cost analyses do not include the lost value of the lands or the costs from harm to future generations or the environment. Ultimately, the costs of these alternatives would prove to be much greater than removing and cleaning up the wastes, as called for by the preferred alternatives.

Response DOE and Ecology acknowledge the preference expressed in the comment and will take this preference and other public comments into consideration when making a final decision on remediating the TWRS waste. Please refer to the response to Comment number 0040.01 for a discussion of factors influencing the evaluation of alternatives. Analyzing the harm to future generations from an economic standpoint is not included in the EIS; however, lost habitat, health risks, health consequences, and probabilities of accidents to future generations were among the impacts analyzed by DOE and Ecology. Land use commitments are addressed in Volume One, Section 5.7, anticipated health effects in Section 5.11, and comparison of potential consequences from accidents in Section 5.12. For the Final EIS, a Native American scenario was added to the analysis presented in Volume One, Section 5.11. Please refer to the response to Comment numbers 0036.18, 0052.05, 0072.22, 0072.55, 0072.198, 0072.225, and 0072.34 for related discussions..

The information requested in the comment represents a level of detail that DOE and Ecology believe is not necessary for meaningful discrimination among the alternatives.

Comment Number 0081.01

Pollet, Gerald

Comment We are concerned that the Department of Energy falsely inflated the costs of waste removal and glassification options to justify leaving waste in the tanks. We are also concerned that the rate the costs have been presented would erroneously lead policy makers to the conclusion, when combined with the use of erroneous assumptions as to risk, lead to the conclusion that in fact it would be cost affected to leave waste behind.

Response The cost estimates are an equal analysis of the total life-cycle costs of each alternative and reflect the best available cost information given that the engineering is still at a conceptual stage. The estimates are available for inspection by the public in the TWRS EIS Administrative Record. Please refer to the response to Comment number 0081.02 for a discussion of how the repository costs were recalculated for the Final EIS. For responses to specific comments regarding risk assumptions, please refer to the response to Comment numbers 0069.08, 0069.09, 0069.03, 0069.06, 0069.07, 0081.07, and 0069.11.

Comment Number 0081.03

Pollet, Gerald

Comment And what is interesting is it has the least technical question. And the EIS is based, in terms of these costs, costs include a 30 to 50 percent capital cost contingency. This is pretty bazaar. We're spending 10's of millions of dollars on research development design phased approach.

We are spending 10's of millions of dollars on design, which ought to drive down contingencies. 30 to 50 percent contingency is the way Hanford has done business with capital construction projects in the past. It is sinful. It is not going to be able to continue. If we eliminate, and we use different factors for contingency, take a look at the fact that a no separation alternative means you build one plant with the simplest technology, vitrification. You vitrify everything. You don't try to separate. You just vitrify. You do not have to build a multi-billion dollar separation plant. You do not have to build separate low activity and high activity vitrification plants. You could, and this EIS fails to consider the alternative which was eliminated earlier in this process, of having a very simple separation of low activity and high activity, in terms of which melter waste is directed too, at the front-end of such a plant. If we look at the cost issue alone, the no separation option actually drives down into the cost range, and perhaps will compare more favorably than the Ex Situ/In Situ Combination even.

The cost assumptions, as with all other assumptions, are critical. Building in 30 to 50 percent contingencies for one set of options is not acceptable for this type of policy decision making. And we can't afford to continue with 30 to 50 percent contingencies for capital costs at Hanford.

Response As noted in the response to Comment number 0052.04, the use of contingencies in capital cost estimates is standard practice throughout the public and private sector. All of the alternatives presented in the EIS include contingencies in the capital cost estimates. During design development for the alternative selected, the cost estimate would be refined and the contingency reduced. The cost estimate for a large facility would typically have some contingency remaining at the start of construction. The capital cost estimate as well as the contingency estimated for the Ex Situ No Separations alternative is smaller than the Ex Situ Intermediate and Extensive Separations alternatives because one treatment facility is constructed instead of two. The contingency factor for the Ex Situ No Separations alternatives provides an equal presentation to the public and the decision makers. Capital construction costs are also discussed in the response to Comment numbers 0055.06, 0057.06, and 0081.03.

A single facility designed to vitrify both HLW and LAW would not be precluded by the EIS for any of the alternatives that include separation of the HLW and LAW. The impacts associated with a single treatment facility would be bounded by the alternatives presented in the EIS. The separations processes included in the EIS cover a reasonable range of representative technologies. The separation of the waste into HLW and LAW streams is bounded with no separations on the low end, extensive separations on the high end, and intermediate separations in the middle.

The Draft EIS addressed the full range of reasonable alternatives. As the alternative identified in the comment is bounded by the alternatives addressed in the Draft EIS, DOE and Ecology believe that including the requested alternative would not provide valuable additional information to the public or decision makers. Please also refer to the response to Comment number 0072.05 for a discussion of the development of the alternatives for analysis in the EIS.

Comment Number 0089.04

Nez Perce Tribe ERWM

Comment Purification and removal of sodium nitrate and other major wastes from tanks prior to segregation of LAW and HLW should be considered for volume reduction and cost savings. Possible removal of sodium nitrate for industrial or certain agricultural use should be considered. Another option may be reacting the sodium nitrate with an organic reducing agent to produce sodium carbonate, nitrogen, ammonia and water, greatly facilitating waste reduction. Options such as these need to be considered to reduce vitrification volumes.

Response DOE and Ecology acknowledge the preference expressed in the comment and will take this preference and other public comments into consideration when making a final decision on remediating the TWRS waste. Volume reduction measures for the waste have been considered, including calcination and the clean salt process. These measures are addressed in Volume Two, Appendix B, Section B.3. Removal of sodium nitrate, such that this compound would be safe and suitable for industrial or agricultural uses would be limited because complete radionuclide removal to form a purified waste would be extremely difficult.

The Draft EIS addressed the full range of reasonable alternatives. As the alternative identified in the comment is bounded by the alternatives addressed in the Draft EIS, DOE and Ecology believe that including the requested alternative would not provide valuable additional information to the public or decision makers. Please refer to the response to Comment number 0072.05 for related discussion.

Comment Number 0090.01

Postcard

Comment Please listen to us say no:

to falsely inflating the cost of glassifying Hanford's High-Level Nuclear Wastes by $211 billion.

Response DOE and Ecology acknowledge the preference expressed in the comment and will take this preference and other public comments into consideration when making a final decision on remediating the TWRS waste. Please refer to the response to Comment number 0040.01 for a discussion of factors influencing the evaluation of alternatives. Please refer to the response to Comment numbers 0004.01, 0009.04, 0008.01, 0038.10, 0081.01, and 0081.02, for discussions regarding how repository costs were calculated and presented in the EIS..

Comment Number 0092.01

Hanson, Mary

Comment I certainly feel that as a lay person, I have every right to the most conservative principles being used in this situation and I certainly, personally and I think I stand for others here, do not consider cost to be important. Money can be made, the environment can not be remade. Now the total defense budget for this country is somewhere around 260 billion dollars per year. That is a lot of waste. In my opinion, that it is throwing money at defense. Most of it. Playing games, testing this and that and so forth. This is a real problem. This is a real security problem and if it were up to me I would put probably half the defense budget on it. So I do not consider money to be something that you can quote, "balance against health." I do not think money is something you balance against the environment. You can not balance a nonrenewable resource like the environment against a renewable resource like money. So I am very strongly in favor that this be done in the economic, in a conservative manner, economically speaking but I certainly feel that if the public really was as aware as everyone in this room is of what the issues are, they would vote very high amounts of money to deal with this threat to our security.

Response DOE and Ecology acknowledge the preference expressed in the comment and will take this preference and other public comments into consideration when making a final decision on remediating the TWRS waste. Please refer to the response to Comment number 0040.01 for a discussion of factors influencing the evaluation of alternatives. Cost estimates presented in the Draft EIS have been reviewed and revised, as appropriate in the Final EIS.

The alternatives and impact analysis presented in the EIS were based on conservative principles, consistent with the requirements of NEPA to bound the potential impacts and to address a range of reasonable alternatives. For more information on this topic, please refer to response to Comment number 0072.05 or in the EIS Volume One, Section 3.3. Please also refer to the response to Comment number 0081.01 for a discussion of issues related to the presentation of costs.

Comment Number 0098.01

Pollet, Gerald

Comment The Department of Energy's presentation tonight and at prior meetings and in these materials show ... say ... claim that this unproven technology of so-called in situ vitrification, sticking electrodes into the ground and melting the ground into glass. The presentation said that this would comply with Washington State law. Nothing could be further from the truth. Washington State first off has in the model toxic control act and our dangerous waste regulations a presumption that we will favor removal. That is the law. Leaving it in place when you have an alternative of removal and retrieval is never allowable under Washington State law. We have a set of priorities for dealing with waste. Hanford does not get to make an exception for itself although it sure does try most of the time.

Response The disposal of HLW by ISV would comply with Washington State law if the hazardous waste components are adequately treated to remove the hazardous characteristics or immobilize the hazardous components. The treatment and disposal would be subject to review and permitting by Ecology. Washington State law does not apply to disposal of the radioactive components of the HLW. For a discussion of regulations applicable to the HLW, see Volume One, Section 6.1. For related discussion regarding technical uncertainty, please refer to the response to Comment number 0012.04. Because the information contained in the Draft EIS is correct, no change to the text was made.

L.3.4.2.3 Assumptions

Comment Number 0005.39

Swanson, John L.

Comment The paragraph beginning at the bottom of page 3-31 is interesting. It starts out by saying that the residual contaminants would be insoluble, and then goes on to make the conservative assumption that 1 percent of the water-soluble contaminants would also be present. This conservative assumption drives conclusions, as discussed in (18) above [Comment number 0005.18].

Response DOE and Ecology recognize the concern expressed in the comment regarding conservative assumptions used in the impact analysis and the extent to which these assumptions affect the calculated risk values. The analysis performed for the Draft EIS assumed, for the ex situ alternatives, that 1 percent of the original inventory would remain in the tanks as residual waste that could not be retrieved. This assumption is bounding (e.g., provides a reasonable upper limit) with respect to the impact analysis, because it includes 1 percent of the water soluble contaminants. The Final EIS has been revised to include Volume Five, Appendix K, which will provide a nominal case analysis using best estimate assumptions. The nominal case analysis was based on 1 percent residual volume that was modified to reduce the inventory of soluble constituents. Using this assumption will result in a risk range and will enable the reader to see the variation in the long-term risk as a function of nominal and bounding assumptions. Please refer to the response to Comment numbers 0072.59, 0072.51, and 0072.05.

Comment Number 0005.40

Swanson, John L.

Comment On page 3-34 it is said that the assumption of cullet in a matrix material as the waste form for onsite LAW disposal "--provides a conservative analysis of the long-term impacts--." This statement is true only if conservative assumptions were made regarding the performance of the matrix materials. Were those assumptions conservative? Are they spelled out somewhere? (Page 3-66 contains a statement in opposition to the one on page 3-34; "The potential benefits of a matrix material and glass cullet combination as a disposal form are reduced contaminant release rates and--." Thus, the assumption of cullet in a matrix material does NOT provide a conservative analysis of the long term impacts, as is stated on 3-34).

Response In order to bound the impacts associated with the LAW disposal vaults, the releases from the LAW vaults were calculated under the assumption that the matrix material provided no reduction in the release rates from the LAW disposal vaults. DOE and Ecology believe that using a matrix material with glass cullet would reduce the release rates from the LAW disposal system. The two statements do not conflict with each other. Cullet, as opposed to monolithic pours, would be more easily leached; therefore, cullet is considered the more bounding (higher) approach in the environmental impacts analysis. Assumptions associated with release rates and associated impacts to groundwater are discussed in Volume Four, Appendix F.

Comment Number 0005.42

Swanson, John L.

Comment The last sentence on page 3-35 says that it has been determined that a bleed stream would be required to avoid a continuous buildup of Tc-99 in the vitrification off-gas stream. I do not believe that is necessarily true, and wonder who made that determination (and on what basis). The data I have seen indicate that some melters can retain a significant fraction of the Tc in the glass; thus, Tc in the off-gas from such melters would stop building up when that in the feed plus recycle equals that in the glass.

Response DOE and Ecology acknowledge the concern regarding the constituents that would require the use of a bleed stream for the off-gas recycle system. The EIS discussion includes technetium-99 and mercury as representative examples of the type of volatile constituents that could build up in the off-gas recycle streams. The LAW vitrification processes addressed in the EIS are based on a combustion fired melter. This melter type raised the concern regarding retention of volatiles and semivolatiles in the glass during technical review of the Preliminary Draft EIS. The requirements for a bleed stream were noted and included in the EIS.

As indicated in the comment, a bleed stream may not be necessary to avoid a continuous buildup of technetium-99 in the off-gas recycle stream, but based on available information, it appears probable that a bleed stream would be required. The functional requirements and sizing of the off-gas recycle system would be developed during the detailed design phase following selection of an alternative.

Comment Number 0012.20

ODOE

Comment Vitrification of the wastes greatly reduces the risk to the public and the environment. Even the least capable glass waste forms represent a dramatic improvement over the current conditions. Wise selection of pretreatment and segregation options and glass specifications may greatly reduce the long-term costs and risks to the public. These should not however delay decisions to proceed with cleanup and vitrification of Hanford's tank wastes.

There is no assurance that any of the vitrified waste will leave Hanford. As a consequence, it is essential that the vitrified waste contain all of the radioactive wastes for so long as they remain hazardous.

The vitrification alternatives do not specify the physical or chemical properties or requirements for the glass products. There is no specification for how durable the glass waste form must be, or for how long the glass must contain the radioactive wastes. Specifications must require the product glass be durable enough to contain the radioactive components for as long as they remain hazardous. This requirement is relatively easy to meet for short half-life isotopes such as strontium-90 and cesium-137. It is more difficult for long half-life isotopes which easily migrate in water, such as cesium-135, iodine-129, technetium-99, and neptunium-237. These isotopes are volatile and are difficult to incorporate into glass. Additionally, the long lived actinides also must be retained until they are no longer hazardous.

The common glasses used for the immobilization of high-level nuclear waste are not durable enough to contain these materials for the times needed. The borate content of these glasses is often controlled at high levels to reduce the melt temperature of the glass and to lower its viscosity. As the borate content is increased, the durability of the glass decreases. Glasses are attacked by organic acids such as humic and fulvic acids from the decay of vegetation which are often found in surface waters. Because the repository is expected to be deep underground, the water which may reach the repository is unlikely to contain large amounts of organic acids. Accordingly, the performance and durability studies of waste glasses for disposal to a national high-level nuclear waste repository have not analyzed the impact of organic acid corrosion on glass wastes, however this is particularly important if the glass waste remains at Hanford and may be subject to corrosion by surface waters.

If the durability of the glass cannot be assured and other barriers provide inadequate protection for the glassified wastes which may remain at Hanford, the radioactive isotopes with half-lives over one thousand years should be removed from the water soluble fraction of the wastes. These should be incorporated into better waste forms, or blended and glassified with the waste which will be sent to the national high-level nuclear waste repository. These isotopes include cesium-135, iodine-129, technetium-99, neptunium-237, and all long half-life actinides.

The durability requirements for glassified wastes to be sent to the proposed national high-level nuclear waste repository are not sufficient to assure protection of human health and the environment at Hanford. The physical conditions onsite are vastly different, and the geologic isolation provided by a deep repository is not available. The EIS must consider changing climate conditions. Hanford cannot be assumed to remain an arid area for as long as these wastes remain hazardous.

As the geologic barrier is not present at Hanford, and the glass wastes may exhibit more rapid corrosion from surface water, additional barriers to contain the waste should be included. The containers for the glass should be of sufficient chemical resistance and durability to protect the glass from the environment for as long as the wastes remain hazardous. The containers should be resistant to corrosive attack and embrittlement from exposure to the glassified wastes. Welding or other sealing of the containers should be done in such a manner as to avoid creating brittle areas in the container. Embrittled containers are likely to fail far more quickly.

Type 309 and 304L stainless steels have been proposed for use at Savannah River and West Valley, New York for containing glassified waste. High-carbon 309 stainless steel is easily embrittled by chloride ions. It should not be used. Low-carbon 304L stainless steel has insufficient molybdenum content to allow long term corrosion protection from the waste. If corrosion resistant stainless steel is used, it should contain at least three weight percent molybdenum to minimize corrosion from chloride and fluoride. It should also be very low carbon steel. Other high resistance alloys should be considered.

Response The alternatives presented in the Draft EIS provide a range of treatment, including disposal of HLW onsite as part of the in situ and combination alternatives. To be consistent with current national policy, all ex situ alternatives that include retrieval and treatment of the tank wastes are based on the assumption that the HLW would be disposed of in a geologic repository. The EIS does analyze permanent near-surface disposal of LAW under the ex situ and combination alternatives and disposal of HLW in place under various in situ and combination alternatives. To address public concerns with the availability of the geologic repository, all ex situ alternatives have been revised in Volume One, Section 3.4 to include interim onsite storage of the immobilized HLW for 50 years.

The ex situ alternatives that produce borosilicate HLW glass comply with the DOE OCRWM Waste Acceptance Systems Requirements document, which requires that the waste form meet performance criteria. The alternatives that do not produce a borosilicate HLW glass are identified as non-conforming to the geologic repository and are potentially not as acceptable and require resolution to make them acceptable which would make them subject to delayed acceptance.

Alloy specification for the HLW canisters would be accomplished during final design of the waste package. Embrittlement, corrosion, and material incompatibility are issues that will be evaluated during canister design and material selection. However, please note that the HLW canister presently has no long-term disposal function. This function is allocated primarily to the waste package disposal container.

DOE and Ecology acknowledge that technical issues requiring evaluation remain before the long-term impacts associated with permanent near-surface disposal of canistered HLW can be assessed. Please refer to the response to Comment numbers 0008.01 and 0008.02.

Comment Number 0019.04

WDFW

Comment The author states that "for the analysis performed in this EIS, a Hanford barrier was used to bound impacts." At this point in time, a cursory effort to bound impacts (resources) of a Hanford barrier should only require volume of soil needed and/or potential acreage impacted. A supplemental EIS can discuss borrow sites and alternatives.

Response DOE and Ecology acknowledge the concern expressed in the comment. However, the Hanford Barrier is the most extensive system for a surface barrier proposed for use on the Hanford Site. The assumption to apply this multi-layered barrier technology serves as the basis for comparison of the impact of changes within an alternatives, as well as between alternatives. The selection of borrow sites is an issue that would be addressed for tank farm closure which will be the subject of a future NEPA analysis. Please refer to the response to Comment number 0019.03. Because the information contained in the Draft EIS is correct, no change to the text was made.

Comment Number 0027.11

Roecker, John H.

Comment Waste Oxide Loading

The use of a 20 percent waste oxide loading is overly conservative and biases the alternatives analysis. A waste oxide loading of 25 percent has normally been used for design and analysis purposes. Studies are also underway for loadings in the 30-35 percent range.

Response The TWRS EIS uses bounding assumptions for HLW oxide loadings for all ex situ alternatives to provide a comparable and bounding analysis in the absence of definitive information. DOE and Ecology are aware that higher HLW oxide loadings have been used for process design and acknowledge, in Volume One, Section 3.4 of the EIS, that current development work may result in higher waste loading factors. Given the uncertainty associated with the characterization data and assumptions made for separations efficiencies, DOE and Ecology believe that a 20 weight percent waste oxide loading is a reasonable assumption for the purpose of calculating impacts. Waste loading is also discussed in the response to Comment numbers 0035.04 and 0027.11. Because the information contained in the Draft EIS is correct, no change to the text was made.

Comment Number 0040.02

Rogers, Gordon J.

Comment The 100-year limit for retaining administrative control is ridiculous, and is not applied to any other human activity.

Response Federal regulations (40 CFR 191) state that to provide the confidence needed for long-term compliance with the requirements for the disposal of HLW, active institutional controls over disposal sites should be maintained for as long as is practical. However, institutional controls are limited to 100 years when considering the isolation of the wastes from the accessible environment. As is stated in Volume One, Sections 3.4.2 and 3.4.3, the 100-year period is an assumption that has been applied to all alternatives analyzed in EIS to provide an equitable basis for comparison of impacts among alternatives. As required by the regulations, the administrative controls would be maintained by DOE and Ecology as agencies of the Federal and state governments. For related discussions, please refer to the response to Comment numbers 0101.01 and 0040.03. Because the information contained in the Draft EIS is correct, no change to the text was made.

Comment Number 0052.01

Pollet, Gerald

Comment Going to start tonight by asking that a little more attention be paid in the materials and the Final EIS through the advice of the Tank Waste Remediation System Task Force. The Task Force urged the three agencies from our putting together this EIS to explicitly not utilize a hypothetical repository in assessing costs and it is nice to go right after someone else whose commented on the same issue.

The TWRS Task Force said we have to assume canisters stay at Hanford. That is not only a reasonable alternative, unfortunately it is the realistic alternative, and it is not appropriately considered in the EIS. So what we need to see is - what are the long-terms costs and impacts from having canister storage here at Hanford.

Response The Tank Waste Task Force report recommended that DOE "accept the fact that interim storage, at least, of the waste in an environmental safe form will occur for some time at Hanford." The report also directed DOE to "assume temporary storage will occur at Hanford but did not assume that all radionuclides should be here forever" (HWTF 1993). The EIS, for all ex situ alternatives, assumes interim storage at the Hanford Site in an environmentally safe manner for up to 50 years and ultimate disposal of HLW offsite at the potential repository. If HLW storage extended beyond 50 years, appropriate NEPA review would be required. Please also refer to the response to Comment numbers 0035.04, 0081.02, 0038.10, 0008.02, and 0004.01 for related information.

Comment Number 0062.03

Longmeyer, Richard

Comment We've talked a little bit about the new tanks that are being filled with wastes from current tanks that are leaking. That also raises a safety concern in that, as was stated, this sludge that remains behind in the single-shell tanks that did leak, actually becomes more dangerous than when there was water in the tank. Dangerous in terms of the material itself, and danger of actual exposure to the outside from explosions, and so forth. So that is a concern.

Response A description of the saltwell pumping program, which is a required action under the Tri-Party Agreement, is provided in Volume One, Section 3.4 and Volume Two, Appendix B. An analysis of safety issues is performed prior to removing liquids to ensure that removal can be performed safely. The SSTs in question that have been pumped have been included in the accident and consequence analysis presented in Volume One, Section 5.12 and Volume Four, Appendix E. The unit liter doses from these tanks were compared with the unit liter doses from the rest of the SSTs and all of the DSTs. The bounding unit liter doses were used to calculate the consequences to bound the analysis.

Comment Number 0064.01

Roecker, John H.

Comment The second point I'd like to bring out is what I call data manipulation. There are examples throughout the EIS where data has been, what I call, manipulated to present a specific case, or to present certain agendas. I can give you some examples, in fact I will give you written comments on the ones that I have found. But as an example, where you talk about the high-end and the low-end of the number of canisters for the two different processes. The low-end you reference a Westinghouse document, and for the high-end you reference a DOE document. Being a little suspicious, and having a little experience with what was going on, I went back to look at those specific documents. The Westinghouse document is an engineering document, which has some pretty good estimates in it. The DOE document is a review of a systems requirements document of DOE that had a high number in it to make some very specific points. To use those numbers in the EIS, I think, is misleading. Because they do not accurately represent the engineering and technical data that is available.

Response The EIS presents an unbiased assessment of the potential impacts associated with each alternative. Please refer to the response to Comment number 0027.02 for a discussion of this same issue and Comment numbers 0081.02, 0008.01, 0069.04, 0035.04, and 0038.10 for a discussion of cost estimates.

Comment Number 0072.85

CTUIR

Comment P3-31: PP1: It should be assumed that there will be leaks and more leaks from the SSTs and DSTs during the administrative control.

Response DOE and Ecology realize that it is difficult to accurately predict the number or severity of tank leaks that will occur in the future. There are factors that will increase the number of leaking tanks, primary of which is the age of the tanks. As the tanks get older, the probability of a leak increases. There also are factors that will decrease the number of leaking tanks. The primary factor in decreasing leaks is the interim stabilization of the tanks by removal of the free liquid from the pore space and other voids in the tank solids; sealing the entrances to the tanks to prevent fresh liquid from accidentally entering the tanks; and placing covers over the tanks to inhibit the infiltration of precipitation. Once these measures are in place, leaks from the tanks would be very small. Because there was no inherently accurate method of determining future leaks, the assumption was made that at some predetermined time in the future (after the loss of administrative control), all the tanks of a given type would leak. This assumption allows an equitable comparison of the long-term environmental impacts of the various proposed alternatives. Please refer to the response to Comment numbers 0005.37, 0029.01, and 0072.70 for related information.

Comment Number 0072.86

CTUIR

Comment P 3-31: PP: Is the required depth to ground water, in the case of leaking tanks, at the minimum to the bottom of the leakage? Or is the required depth from the bottom of the tank? Please explain this with a description of the reasoning involved.

Response Releases for the tanks, whether from in situ or ex situ alternatives, are assumed to be from the bottom of the tank. This is a bounding assumption that results in the highest predicted contaminant concentration in groundwater.

Comment Number 0072.88

CTUIR

Comment P 3-31: PP 6: The efficiency goal should state no more than 1 percent of the solid-dry tank inventory would remain as a residual and no more than .1 percent liquid tank inventory remain as a residual following waste retrieval activities.

Response The Tri-Party Agreement (Ecology et al. 1994) includes a milestone that directly impacts the TWRS program. Milestone M-45-00 requires tank residues not exceeding 10.2 m^3 (360 ft^3) in each 100 series tank, and tank residues not exceeding 0.85 m^3 (30 ft^3) in each 200 series tank. This milestone provides the basis for the TWRS EIS assumption of 99 percent removal for ex situ alternatives. An overview of retrieval and transfer from the tanks is provided in Volume Two, Section B.3.5.3. Further evaluation of the residual inventory would be performed in a future NEPA analysis on closure of the tank farms. Please refer to the response to Comment number 0089.03, 0089.07, and 0005.18 for related residual waste information. Because the information contained in the Draft EIS is correct, no change to the text was made.

Comment Number 0072.89

CTUIR

Comment P 3-34: PP 7: Assuming that a LAW activity waste cullet provides the basis of conservatism is wrong. The technical staff of the SSRP suggests that all LAW waste be vitrified into glass and poured into canisters for the lowest risk levels.

Response DOE and Ecology acknowledge the preference expressed in the comment and will take this preference and other public comments into consideration when making a final decision on remediating the TWRS waste.

The referenced language in Volume One, Section 3.4 is a discussion of waste composition for the various alternatives. A disadvantage of cullet is its high surface to volume ratio, which results in lower long-term performance. Therefore, the calculations of leach rates are higher (more bounding from an impact assessment standpoint) for cullet than for other glass forms. In the area of long-term environmental impacts, this lower long-term performance manifests itself as greater amounts of contaminants leaching from the cullet. Changing to another waste form that would have potentially better long-term performance may be achieved during the final design of the alternative selected. Because the information contained in the Draft EIS is correct, no change to the text was made. Please refer to the response to Comment number 0005.40.

Comment Number 0072.90

CTUIR

Comment P3-3: PP 8: The public has stated numerous times that grout for use as a way of stabilizing tank waste in any form is unacceptable.

Response DOE and Ecology acknowledge the preference expressed in the comment and will take this preference and other public comments into consideration when making a final decision on remediating the TWRS waste. Please refer to the response to Comment number 0040.01 for a discussion of factors influencing the evaluation of alternatives. Grouting liquid waste streams is included in Volume Two, Appendix B as a reasonable immobilization technology in the EIS; however, it is not a technology included in the preferred alternative. For a discussion of NEPA requirements to analyze reasonable technologies, please refer to the response to Comment number 0072.05. Grout is discussed in the response to Comment numbers 0005.18, 0009.03, and 0072.179.

Comment Number 0072.178

CTUIR

Comment P B-37: Sect.B.3.0.6: Please explain how soda lime glass can be upgraded to the standards of the only standard HLW form, borosilicate glass in terms of leachability, thermal-breakdown, expansion, and ability to capture and isolate radionuclides.

Response Soda-lime glass would have different characteristics than borosilicate glass in terms of leachability, thermal expansion, and physical processing parameters. As stated in Volume Two, Section B.3, borosilicate glass currently is identified as the only standard HLW form to be accepted at the potential geologic repository. Other types of glass could be selected for the vitrification of HLW or LAW; however, they would have to meet the NRC waste form requirements and support the repositories ability to meet long-term performance requirements.

Under the Ex Situ No Separations alternative, all of the sodium present in the tank waste would be included in the vitrified waste stream. Because of this, the glass more closely approximates a soda-lime glass. The repository Waste Acceptance Systems Requirements Document currently includes only borosilicate glass as an acceptable glass composition; however, it identifies that other waste forms may be addressed in the future. The acceptability of alternative glass compositions would be based on waste form performance testing. Please refer to response to Comment numbers 0012.20, 0012.11, and 0035.04 for a related discussion.

Comment Number 0072.179

CTUIR

Comment P B-38: The use of grout is unacceptable and has been thoroughly denounced by the public. The grouting of LAW which will contain discrete particles of hi-activity radionuclides is unacceptable.

Response DOE and Ecology acknowledge the preference expressed in the comment and will take this preference and other public comments into consideration when making a final decision on remediating the TWRS waste. Please refer to the response to Comment number 0072.90, which addresses the consideration of grout as a waste form in the EIS.

Comment Number 0072.194

CTUIR

Comment P B-157: Sect. B.5.0: The information on how closure activities would affect remediating the tank waste should include carrying all of the listed closure options through the alternatives process in order to adequately present the information. Simply choosing a single representative approach to tank closure (closure as a landfill) is insufficient and in the light of the importance of this retrieval EIS. The closure options presented must indicate whether they do or do not preclude one or more of the alternatives. Additionally the closure options must necessarily conform to the law ALARA conditions for the purposes of reducing risks to future generations. This information is simply not here and raises doubt that the representative approach is truly representative.

Response Please refer to the response to Comment number 0072.08 for a discussion of the reasons closure alternatives cannot be assessed at this time and 0072.50 for information on alternatives that would preclude closure options. Closure of the tank farms will be addressed in a future NEPA analysis when sufficient information is available on past practice releases, releases during retrieval, and tank

residuals. Please refer to the response to Comment number 0101.06 for a discussion of issues related to analysis that would be required to support closure alternatives analysis. Because the analysis requested in the comment is not within the scope of the EIS, no modification to the document is warranted.

Comment Number 0072.195

CTUIR

Comment P B-158: Sect. B.6.0: The inclusion of the Hanford Barrier and the exclusion of all other closure activities may preclude adequate justification of the alternative section due to the fact that providing one option is not providing a choice of options. Please insert the other closure activities options or remove section B.5.0 tank closure because it is not within the scope of this EIS.

Response Closure is not included in the scope of this EIS because there is insufficient information concerning the amount of contamination to be remediated. However, Volume One, Section 3.3 and Volume Two, Section B.5 address how tank waste remediation and closure are interrelated because some of the decisions made regarding how to treat and dispose of tank waste may impact future decisions on closure. To provide information on how closure activities would be affected by remediating the tank waste, a representative approach to tank closure (closure as a landfill) has been included in each of the TWRS alternatives to allow an equitable comparison of the alternatives. The Hanford Barrier described in Volume Two, Section B.6 is included as a representative approach to tank closure. Please refer to the response to Comment numbers 0101.06, 0019.03, 0019.04, 0052.01, 0072.50, and 0101.05 for related discussions. Because the analysis requested in the comment is not within the scope of the EIS, no modification to the document is warranted.

Comment Number 0081.04

Pollet, Gerald

Comment The Tank Waste Task Force, convened by the Department of Energy, U.S. EPA, and Washington Department of Ecology, urged that the Department of Energy abandon making decision making on the basis of high-level nuclear waste canisters, and their theoretical costs for being placed into a repository. Our advice was, now I need to turn to the appropriate page, on page 11 of the Task Force Report under Values, under Waste Form and Storage. Let the ultimate best form for the waste drive decisions, not the size or timing of the national repository. This EIS has failed to consider that advice.

Response DOE and Ecology acknowledge the preference expressed in the comment and will take this preference and other public comments into consideration when making a final decision on remediating the TWRS waste. Please refer to the response to Comment numbers 0081.02, 0008.02, 0035.04, 0038.10, and 0052.01 for a discussion regarding task force advice.

Comment Number 0089.03

Nez Perce Tribe ERWM

Comment Listed below are our general statements regarding the EIS.

Some necessary topics are not properly considered in the EIS. An example is the proposal to leave 1 percent of the waste in the tanks. We believe that with the technology currently proposed, if 99 percent of the waste can be removed, then it is also possible to remove much of the remaining 1 percent of the tanks wastes. This question will definitely be pursued by ERWM during soil and groundwater remediation, which are not part of the EIS. For proper soil remediation, beneath the tanks following closure or tank removal, it is imperative that no waste be left in the tanks.

Response The amount of residual waste that ultimately remains after retrieval will depend on the effectiveness of the retrieval technology. For the purposes of NEPA analysis, the assumption that 1 percent of the waste would remain in the tanks was assumed in the EIS analysis. For a discussion of this issue, please see the response to Comment numbers 0005.18 and 0089.07. Further experience with waste retrieval will be required before the issue of the extent of retrieval can be fully resolved. Please refer to the response to Comment numbers 0101.06, 0072.08, and 0072.88 for related information concerning tank waste residuals, soil and groundwater contamination, and closure.

L.3.4.2.4 Miscellaneous Issues

Comment Number 0005.41

Swanson, John L.

Comment The word "grouting" at the start of the last paragraph on page 3-34 appears to be out of place, and appears to belong instead at the start of the first paragraph on the next page.

Response "Grouting" does belong with the paragraph at top of page 3-35 of the Draft EIS. The two sentences following the word "grouting" are out of place. The text of the Final EIS has been corrected.

Comment Number 0005.43

Swanson, John L.

Comment On page 3-36 is discussed the use of sodium from the FFTF to make sodium hydroxide for use during enhanced sludge washing. Is this really worthy of mention? Was the cost of conversion of sodium to sodium hydroxide (which has some safety problems) included in the cost estimates?

Response Fast-Flux Test Facility (FFTF) sodium disposal is worthy of mention because of the potential amount of material that may require disposal considerations in the near future. A cost analysis of the conversion facility and the process safety issues were not performed and would need to be addressed before a decision was made to use FFTF sodium as a source of material for separations chemicals. The use of sodium from FFTF was included in the EIS as an example of Sitewide waste minimization activities that could be considered.

Comment Number 0008.04

Evett, Donald E.

Comment On the subject of groundwater, I believe the method of retrieval using the articulated arm to reach into the tanks and recover waste would be an excellent method and it would reduce the amount of leakage, which is of paramount importance.

Response DOE and Ecology acknowledge the preference expressed in the comment and will take this preference and other public comments into consideration when making a final decision on remediating the TWRS waste. As indicated in Volume One, Section 3.4, the articulated arm retrieval method would be used in situations where conventional technology is not effective or inefficient for the particular tank waste type or form. Using the articulated arm technique and others is also key to removing as much of the tank waste as possible to minimize or eliminate any materials that could be released to the environment. DOE and Ecology will analyze the data collected during the demonstration phase to select the most effective removal method for the tank and tank waste type.

Comment Number 0068.03

Martin, Todd

Comment The last point I want to make is that a clear lesson that we've learned from Hanford and from the nuclear weapons complex is that postponements and delays lead to greatly increased obligations in the future. We've learned that in spades, at least I hope we've learned that. And I'm not sure that the Federal government has learned that. The American people are certain of that. That means we need to get on with it now, otherwise it's going to cost that much more in the future.

Response DOE and Ecology share the desire to proceed with remediation at the earliest possible date. Delays can be costly. DOE intends to allow sufficient time to design adequate actions that are supported by factual information, that incur a reasonably acceptable level of technical risk (i.e., high probability that the action will work and accomplish the desired result), and that are implemented in a managed and cost-effective way. Please refer to the response to Comment numbers 0009.19, 0060.02, 0098.02 and 0078.07.

Comment Number 0072.82

CTUIR

Comment P 3-27: Sect. 3.4.1.1: First bullet: What exactly is "managing operations" and are these the operations included in the 1997 RDS for fail-safe management?

Response Managing operations, as listed in the first bullet in Volume One, Section 3.4, includes the activities listed in the bullets that follow as well as tank farms and associated facilities management (as a program), and the relationship of the TWRS program to the Hanford Site Operations system. Consequently, the management issues relevant to each activity (e.g., personnel, safety, quality, and milestone status) are relevant on a programmatic level across Tank Farm Operations. Tank farms management is one operation described in the 1997 Risk Data Sheet (RDS) for fail-safe management. The 1997 RDS was prepared for the Hanford Site as a single operation.

Comment Number 0072.83

CTUIR

Comment P 3-28: PP 4: how much exactly will these controls increase the cost of maintenance and monitoring activities.

Response The operating cost and schedule impacts associated with placing all 177 tanks under flammable gas controls (if this were to occur) is not fully known at this time. One of the factors that will influence the cost and schedule impacts would be resolution of the flammable gas safety issue for the tanks.

Comment Number 0072.87

CTUIR

Comment P 3-31: PP 4: How can you fill a tank full of liquid with rocks and not have liquid overflow?

Response As discussed in the description of the alternatives in Volume One, Section 3.4 and Volume Two, Appendix B, for the In Situ Fill and Cap alternative, as much water as possible would be removed from the liquid waste streams through evaporation at the 242-A Evaporator. The amount of water that can be removed from a liquid waste stream at the evaporator is limited by the saturation concentration of the evaporated waste stream. Following transfer of the evaporated liquids back to the tank, salt-cake formation would begin in the DSTs similar to what has already happened with the DSTs. This would allow for additional evaporation of the liquids. If the In Situ Fill and Cap alternative were selected for implementation, further analysis may indicate a need for additional evaporation using in-tank technologies for selected tanks.

Comment Number 0072.91

CTUIR

Comment P 3-36: PP 1: Exactly what is "some low temperature process"? How much will this process cost? Is this process figured in the privatization process, and what are the risks associated with this? How much extra waste is going to be generated with this process? What will this waste be classified as?

Response Calculations performed for the Ex Situ Intermediate Separations alternative off-gas recycle bleed stream resulted in an estimate of 3,500 m^3 (930,000 gallons) of liquid waste. This waste stream would be dilute and the volume could be reduced by evaporation. The stabilization of this waste stream would require a low-temperature stabilization and treatment technology such as encapsulation, hydraulic cements, or organic polymers to immobilize the waste and limit further volatilization. The development and selection of this process would occur during the detailed design phase. An individual cost estimate for this process was not included in the alternative cost estimates developed for the EIS. The cost would be minor compared to the total alternative cost and would be well within the estimated cost range.

Each of the alternatives that involve high temperature waste treatment technologies, such as vitrification, would have to deal with the volatile chemical and radionuclide emissions in the off-gas system. The risks during remediation are included in the analysis performed for each of the alternatives in Volume One, Section 5.11 for health impacts during remediation. The post-remediation risks that would result from disposal of the stabilized off-gas recycle bleed stream is assessed in the Performance Assessment for the Disposal of Low-Level Waste in the 200 West Area Burial Grounds.

An estimate for the total volume of immobilized waste that would be generated has not been made for the alternatives. A volume estimate would be made during the detail design phase when the characteristics of the bleed stream were developed and the immobilization technologies were evaluated.

Following stabilization, this waste stream would be classified as LAW. The classification and handling of this waste stream would be consistent with established Hanford Site solid waste disposal practices.

Comment Number 0072.180

CTUIR

Comment P B-39: S 2: Please explain how the amount of tertiary waste generated would be primarily a function of the number of operating personnel.

Response The primary component of tertiary waste is personal protective equipment. Therefore, because the number of operating personnel required to wear personal protective equipment when the potential exists for contact with hazardous or radioactive substances is higher for the alternatives that include the more complex remediation activities, the amount of tertiary waste generated also would be higher.

Comment Number 0089.05

Nez Perce Tribe ERWM

Comment Offsite disposal of LAW should be considered in the EIS.

Response DOE and Ecology acknowledge the recommendation expressed in the comment. Offsite disposal of all waste at the potential geologic repository is addressed in the EIS under the Ex Situ No Separations alternative. Offsite disposal of the LAW was not considered to be a reasonable alternative because of the cost and human health impacts of transporting the waste and because there would be no compensating benefits to offsite disposal. Please refer to the response to Comment number 0005.03 for a discussion of the assumptions used in the alternative analyses.

Comment Number 0089.11

Nez Perce Tribe ERWM

Comment Page B-72, Paragraph 1

We have some questions about the plan for the cross-site transfer line. Apparently this line will be sloped to at least 0.25 percent grade to preclude accumulation of solids. ERWM questions the thought behind those plans, the elevations at 200 West and 200 East are nearly the same but 5 miles apart. How will the line be constructed and this slope engineered?

Response Specifications for the cross-site transfer line are not included in the scope of this EIS; however, the SIS Final EIS addresses the cross-site transfer line in detail (DOE 1995i). The SIS EIS was referenced during preparation of the TWRS EIS. According to the SIS EIS, the line would slope up from the 200 West Area to a midpoint, and then down to the 200 East Area to ensure that the line will drain.

L.3.4.3 No Action Alternative (Tank Waste)

Comment Number 0072.94

CTUIR

Comment P 3-40: Sect 3.4.2: No Action Alternative: Technical staff of the CTUIR do not agree that this alternative is a responsible action, given that the contents have half lives that number in the thousands.

Response DOE and Ecology acknowledge the preference expressed in the comment and will take this preference and other public comments into consideration when making a final decision on remediating the TWRS waste. Please refer to the response to Comment number 0040.01 for a discussion of factors influencing the evaluation of alternatives.

NEPA requires that all reasonable alternatives be evaluated, regardless of cost, compliance to existing regulations, potential risk, or any other factor used in the analysis of alternatives. Furthermore, the CEQ requires that the TWRS Draft EIS identify and analyze a range of reasonable alternatives for the proposed action, as well as for the No Action alternative. All data that support the cost and impact analysis of each alternative are presented in an objective and unbiased format for comparison by the decision makers and the public during the comment period. Please refer to the response to Comment numbers 0072.80 and 0072.10 for more information concerning the No Action alternative and NEPA requirements for reasonable alternative analysis.

Comment Number 0072.181

CTUIR

Comment P B-41: Sect. B.3.1: A one hundred year administrative control period does little to protect human health and environmental impacts from long lived (>10,000 year 1/2 life radionuclides).

Response Although DOE has no plans to abandon the Site after 100 years, it is not reasonable to assume that administrative controls will extend to 10,000 years. In order to show potential impacts that could occur if administrative controls were lost, a 100-year administrative control period was assumed. This assumption is consistent with standard impact assessment methods for hazardous and radioactive waste sites. Please refer to the response to Comment numbers 0072.80, 0040.02, and 0101.01 for discussions related to DOE assumptions associated with the 100-year administrative control period and the analysis of long-term impacts resulting from the loss of institutional controls.

Comment Number 0072.182

CTUIR

Comment P B-43: Sect. B.3.1.4: Please insert the statement 'some tanks may not last fifty years'.

Response Volume Two, Appendix B addresses actions that would be taken in the event that a tank leaks within the estimated design life of 50 years, as well as the integrity testing to be conducted within any applicable 50-year design life. "Continued management would include maintaining spare DST space to accommodate leak recovery in the event of a DST leak. Tank conditions would be continually monitored, and those tanks determined to be leaking would require recovery of the leakage from the tank annulus." Because the information requested in the comment was included in the Draft EIS, no modification to the document is warranted.

L.3.4.4 Long-Term Management Alternative

Comment Number 0038.01

Reeves, Merilyn

Comment I would like to point out that one of the things that the Hanford Advisory Board did was to commission a special report, a report to look at whether or not we should build six new massive tanks, double-shelled to hold waste because we were not looking at any other end point.

A report was prepared by Dr. Glen Paulsen, Dr Frank Parker, and Dr. Michael Cavanaugh, noted experts in the field.

And from this report it became clear that they recommended that no new monies be spent for the construction of new tanks to store the tank waste at Hanford.

The Board adopted this. This is a savings of approximately 300 to 400 million depending on which report you look at.

I think that this also puts in place the Long-Term Management alternative in the EIS that would have required replacement of all the double-shelled tanks in the year 2035, and again in the year 2085.

And so I believe that our consensus advice, which was listed as consensus advice number 22 in which we endorsed the recommendations of this report should put to rest whether or not we should embark on any scheme to just continue to build double-shell tank for storage of these wastes.

Response DOE and Ecology acknowledge the preference expressed in the comment and will take this preference and other public comments into consideration when making a final decision on remediating the TWRS waste.

NEPA requires DOE and Ecology to examine a full range of alternatives in the EIS. The range of alternatives must include a No Action alternative and then may include other reasonable alternatives to allow an analysis of a full range of alternatives. Within the range of considered alternatives is the Long-Term Management alternative, which contains the provision for building two sets of DSTs at 50 and 100 years in the future. Including this alternative in the EIS serves a useful purpose, because while it does not contain provisions for immobilizing the tank waste, it does contain provisions for maintaining the SSTs in a relatively dry condition and for retanking the wetter DST wastes on a periodic basis. Please refer to the response to Comment number 0072.05 for a discussion of how the alternatives were developed to comply with NEPA requirements to analyze a range of reasonable alternatives.

Comment Number 0072.95

CTUIR

Comment P 3-43: PP: The argument for long term management seems poor given that a large amount of SST waste has already leaked to the ground, and that the transfer of tank waste simply for maintenance reasons has inherent risks that are unacceptable.

Response DOE and Ecology acknowledge the preference expressed in the comment and will take this preference and other public comments into consideration when making a final decision on remediating the TWRS waste.

NEPA requires that all reasonable alternatives be evaluated, regardless of cost, compliance to existing regulations, potential risk, or any other factor used in the alternatives evaluation process, which would include the Long-Term Management alternative evaluated in the EIS. Please refer to the response to Comment numbers 0072.05 and 0038.01 for related discussions. All data that support the cost and impact analysis of each alternative are presented in an objective and unbiased format for comparison by the decision makers and by the public during the comment period. DOE and Ecology are aware that the vadose zone has been contaminated beneath the tanks. Existing contamination is presented in Volume One, Section 4.2, and cumulative impacts of existing contamination, TWRS alternatives and other Hanford Site actions are presented in Volume One, Section 5.13. The potential risks associated with moving waste from one tank to another one are analyzed in the EIS in Volume One, Section 5.11 and Volume Three, Appendix D for routine operations during remediation and Volume One, Section 5.12 and Volume Four, Appendix E for accident risks.

Comment Number 0072.96

CTUIR

Comment P 3-45: Sect. 3.4.3.5: Post Remediation: this section needs to have an account of the remediation of the extra ground used.

Response This comment refers to the post remediation section for the Long-Term Management alternative. The extra ground would be the surface area overlaying the 26 new DSTs that would be constructed as part of this alternative. As explained in Volume One, Section 3.4.3.1, this alternative is similar to the No Action alternative in that administrative controls over the Hanford Site are assumed to be maintained for 100 years. No remediation activities would be performed. The consequence is stated in Section 3.4.3.5 that there would be no post-remediation activities associated with the Long-Term Management alternative. Because there is no remediation of the extra ground, no account of this activity has been provided in the EIS.

Comment Number 0072.183

CTUIR

Comment P B-44: Is there a sludge well pumping operation ongoing?

Response DOE and Ecology believe that the comment is referring to saltwell pumping. Saltwell pumping of the SSTs to remove interstitial liquids is an ongoing operation that is scheduled to be completed in the year 2000. Saltwell pumping is an activity that would be a part of continued operations under all alternatives as indicated throughout Volume One, Section 3.4.

L.3.4.5 In Situ Fill and Cap Alternative

Comment Number 0072.184

CTUIR

Comment P B-48: Sect. B.3.3: This alternative is unacceptable as are all in situ alternatives. Language clearly defining that in situ alternatives are against the law must be inserted here.

Response DOE and Ecology acknowledge the preference expressed in the comment and will take this preference and other public comments into consideration when making a final decision on remediating the TWRS waste. The Summary, Section S.7, discusses regulatory compliance for each alternative and indicates which alternatives would fail to comply with applicable laws and regulations. Regulatory compliance also is addressed in Volume One, Sections 3.4 and 6.2 and Volume Two, Appendix B. In each of the sections cited, it is clearly stated that this alternative would not comply with certain laws and regulations. Because the information requested in the comment was included in the Draft EIS, no modification to the document is warranted.

L.3.4.6 In Situ Vitrification Alternative

Comment Number 0014.01

Bullington, Darryl C.

Comment It is impossible to take seriously any document that includes a proposal to spend 16 to 23.8 billion dollars and use one-quarter of the available electricity of the Washington Public Power Supply System to vitrify 73 million curies of hazardous radioactive solids and surrounding soils contaminated with thousands of gallons of cesium-137 containing liquid (a volume of over 20,180 cubic yards per tank) to a depth of sixty feet by inserting electrodes and heating to 2,600 to 2,900 F. Before I would even waste the paper to evaluate such a scheme I would have to see some demonstration using noncontaminated materials at a place and in a way that would not be a hazard to the public and people involved. To design any system that could contain all of the gases that would be suddenly released from such an event or a heat shield needed to protect the operating deck above the tanks, and enclosed, should melting such a mass even be possible, is beyond all imagination. To perform such a full-scale demonstration for $70 million is also highly suspect.

Response DOE and Ecology acknowledge the preference expressed in the comment and will take this preference and other public comments into consideration when making a final decision on remediating the TWRS waste. ISV is a commercially available technology that has been successfully demonstrated on a smaller scale and is a reasonable alternative for analysis in the TWRS EIS. The EIS does discuss the technical uncertainties associated with implementing this alternative in the Summary, Section S.7, Volume One, Section 3.4, and Volume Two, Appendix B. Please refer to the response to Comment numbers 0072.80 and 0072.05 for discussion of NEPA requirements for reasonable alternatives analysis.

Comment Number 0023.01

Geosafe

Comment The ISV alternative should provide an objective evaluation for selecting the size of the tank farm containment facility. The confinement facility as shown in Figure 3.4.5, which encloses an entire tank farm, may have some distinct advantages but it poses significant design and construction difficulties. A smaller containment facility could be more easily constructed that encloses only one tank at a time. The smaller facility could be moved into position using a crawler system similar in design to that proposed for the decommissioning of the 100 Area Reactors (WHC MLW-SVV-037106). Two sets of crawlers could be used to move multiple containment facilities. Although not stated in the EIS, it is presumed the need to enclose an entire tank farm was based on the premise that a structural load could not be supported by the dome structure of the tanks and would result in their collapse. For the ISV alternative, the void spaces in the tanks will be filled with sand or other material and can be made suitable for load bearing. The smaller confinement facility would be significantly easier to construct, maintain and decontaminate after project completion. In addition, the smaller facility should significantly reduce the degree of technical difficulty in implementing the ISV alternative and potentially lower its cost as well.

Response Alternative configurations for the tank farm confinement facility for ISV are possible. The configuration proposed in the comment is smaller than the facility depicted in the TWRS EIS. This proposed size reduction ultimately could result in a confinement facility that would be mobile, and could be moved from tank to tank within a tank farm. A large facility would not impose a bearing load on the individual tanks because its perimeter would lie outside of the tank farm. Because a smaller confinement facility potentially would impose a bearing load on adjacent tanks, a design solution to this problem would have to be formulated before the smaller confinement facility could be considered practicable. Filling the adjacent tanks with sand would be among those considered.

One potential problem area not discussed in the comment is the off-gas collection and treatment equipment and facilities. With a large confinement facility, the off-gas would be ducted to stationary treatment facilities. With the smaller, mobile confinement facility, the solution might be to move the off-gas treatment facility when the confinement facility is moved, or alternately, to re-route the off-gas ducting when the confinement facility is moved. This is one of a number of areas where further detailed study potentially could result in an improved process. In these areas of potential improvement, the configuration selected for inclusion in the EIS represented a bounding condition, which would result in environmental impacts that were likewise bounding. These bounding impacts are those presented to the decision makers.

The Draft EIS addressed the full range of reasonable alternatives. The alternative is bounded by the alternatives addressed in the Draft EIS, and DOE and Ecology believe that including the requested alternative would not provide valuable additional information to the public or decision makers. For a discussion of the approach used in the EIS to develop and analyze alternatives, please see Volume One, Section 3.3 and refer to the response to Comment number 0072.05.

Comment Number 0023.02

Geosafe

Comment An objective evaluation should be provided for selecting the size of the ISV equipment. The evaluation should discuss the advantages and disadvantages of using a large ISV system versus using a smaller system more closely resembling commercially available equipment.

The concept of treating a tank with extremely large melts significantly increases the difficulty and the technical Implementability of the ISV alternative. The ISV system proposed in the EIS is 40 times larger (4 Mw vs. 160 Mw) than existing equipment and is capable of treating a tank in one setting. Geosafe believes treating tanks in large settings may pose significant operational problems. We believe a more workable approach is to treat tanks with smaller multiple ISV settings so as to have better control on the release of vapors from in and around the tank.

Another factor to consider with a large-scale ISV systems is power level fluctuations caused by startup or shut down. It is envisioned that power line fluctuations caused by a 160 Mw system may be unacceptable for the regional power grid unless special arrangements are provided.

In summary, smaller ISV units that treat tanks in multiple settings would greatly increase the technical Implementability of the ISV alternative and potentially reduce costs. Schedule requirements could be maintained by using multiple ISV systems operating simultaneously at various tank farms. In addition, the research and development time required for the smaller ISV unit would be significantly shorter than the 160 MW unit.

Response Alternative configurations for the power supply facility for ISV are possible. The configuration proposed in the comment is smaller than the facility depicted in the EIS. A large facility potentially could impose load fluctuations on the regional power grid, although with proper planning these fluctuations could be effectively managed. Because a smaller power supply facility potentially would melt only a portion of a tank and its contents, a solution to this problem would need to be formulated before the smaller power supply facility could be considered practicable. Using multiple power supply units would be one solution among those considered. That multiple smaller power supply units potentially would reduce costs may be premature. For the majority of process equipment, purchasing a single large unit rather than multiple smaller units is generally more economical. To state that the research and development time required for the smaller power supply facility would be significantly shorter than for the larger unit also may be premature. Using multiple ISV settings would allow better control on the release of vapors from in and around the tank also would be considered premature until further studies have been completed. These are a number of areas where further detailed study potentially could result in an improved process. In these areas of potential improvement, the configuration selected for inclusion into the EIS represented a bounding condition, which would result in environmental impacts that were likewise bounding. These bounding impacts are those presented to the decision makers.

The Draft EIS addressed the full range of reasonable alternatives. As the alternative identified in the comment is bounded by the alternatives addressed in the Draft EIS, DOE and Ecology believe that including the requested alternative would not provide valuable additional information to the public or decision makers. Please refer to the response to Comment numbers 0023.01 and 0072.05.

Comment Number 0023.03

Geosafe

Comment Two techniques should be evaluated for reducing the processing depth of ISV which is specified in this document as 60 ft. Implementation of one or both of these techniques will decrease the technical difficulty of implementing the ISV alternative.

The first option would involve the removal of overburden to expose the dome structure of the tank. The overburden could be subsequently added to the tanks to eliminate internal void spaces. This would decrease the required processing depth of ISV to approximately 45 ft for the largest volume tanks.

The second option would involve the intentional lowering of the tank dome structure into the tank to reduce the effective processing depth from 45 ft to 33 ft for the largest tanks. This would be accomplished by first covering the contents of the tanks with an adequate depth of soil to provide radiation shielding. Next the center portion of the tank would be cut into pieces and lowered into the tank on to the soil. Following the removal of the dome structure, additional soil would be placed in the tank to provide a level surface to begin ISV operations. It is recognized that cutting into a tank will present some added risk that will need to be evaluated.

Response Further research and investigation associated with ISV is possible. This particular comment deals with potential solutions to the problem of having ISV operate at depths of approximately 60 feet. The suggestions for using the tank overburden to reduce tank voids; and subsequently lowering the tank dome into the tank before vitrification are examples of areas where further investigation may prove to be of value; however, substantial safety considerations would need to be overcome. Added risk from exposing and cutting into the tanks has not been evaluated. These are several areas where further detailed study could potentially result in an improved process. To address this issue, the cost estimate includes additional costs for technology development for this alternative. In these areas of potential improvement, the configuration selected for inclusion into the EIS represented a bounding condition, which would result in environmental impacts that were likewise bounding. These bounding impacts are those presented to the decision makers. Please refer to the response to Comment number 0023.01.

Comment Number 0023.04

Geosafe

Comment Following treatment of the tanks with ISV, there is no need for the tanks to be capped with the Hanford barrier. A simpler and less expensive cover to minimize the downward percolation of water could be used. The Hanford barrier is designed to provide plant, animal and human intrusion into a waste zone using a thick zone of crushed rock and to prevent the downward percolation of water. Since the ISV monolith is already a rock "cap" of considerable structural strength the need for a biointrusion zone is unnecessary.

Response ISV will leave the tank contents in a form unique to that alternative. However, the remaining waste form is still radioactive and some means must be employed to prevent access by humans, animals, and plants. The Hanford Barrier was used for this purpose as a potential form of closure, which is applicable to all the alternatives. Closure or dispositioning of the tanks is further discussed in Volume One, Section 3.3 and in Volume Two, Section B.5.0 of the EIS. Tank waste remediation and tank farm closure issues cannot be separated; therefore, an assumption common to all alternatives was included in the alternatives evaluation, but not evaluated as a single, specific action. Because the information contained in the Draft EIS is correct, no change to the text was made. Please also refer to the response to Comment number 0019.04 for a discussion of the Hanford Barrier.

Comment Number 0023.05

Geosafe

Comment The ISV cost estimate should discuss the following costing assumptions: (a) are individual tank depths being taken into consideration for estimating treatment volumes, e.g. the 500,000 gal tanks are 18 ft deep and the million gal tanks are 32.5 ft deep, (b) is the area between tanks being vitrified and (c) is soil beneath the tanks being treated.

Response DOE and Ecology have presented life-cycle cost estimates for each alternative. These estimates are based on conceptual designs for the alternatives. Because of the conceptual nature of the alternatives, there is a level of uncertainty associated with the life-cycle cost estimates. To account for the variations cited in the comment, such as variations in tank sizes and variability of the volume of treated material, an uncertainty analysis has been completed for the tank waste alternatives. The resultant cost range for each alternative is shown in Volume Two, Section B.8.0 of the EIS. Other information on the cost estimates is contained in Volume One, Section 3.4.1.7 and Volume Two, Section B.3.0.8 of the EIS. Only the contaminated soil between the tanks and immediately around and below the tanks is assumed to be vitrified. Because the information contained in the Draft EIS is correct, no change to the text was made.

Comment Number 0023.06

Geosafe

Comment Page 3-52, 4th par. "Each vitrification system ... consuming 160 Mw of power." Power consumption rates should be discussed for all alternatives and not be specifically limited to the ISV alternative. ISV is an extremely efficient vitrification technology. On average ISV consumes 800 Kw-hrs of electricity to vitrify a ton of material which is considerably lower than other vitrification technologies. The power consumption rates as listed in Table B.11.0.3 for the ISV alternative is 7,690 Gwh, which is less than the "ex situ no separation" alternative (8,800 Gwh) and the "ex situ extensive separation" alternative (41,600 Gwh).

Response The preliminary calculations used in the EIS show that ISV has a power consumption lower than other alternatives. To provide a side-by-side comparison of the resource consumption of the alternatives, DOE and Ecology have presented the material in summary form in Volume Two, Table B.11.0.3. To provide a complete narrative description in Volume One, Section 3.0, the EIS presents the information for each alternative under six headings: Process Description; Construction; Operation; Post Remediation; Schedule, Sequence and Costs; and Implementability. The Process Description for each alternative describes the major pieces of equipment for each process, giving a description of some of the major equipment used in the process. The section to which the comment refers is the Process Description for ISV, and the power supply was described as one of the major equipment items of this process. For other alternatives, the major equipment items will be different because the process is different. Because this section is a process description, it should not be interpreted as attempting to portray ISV as having obvious advantages or disadvantages. Because the information contained in the Draft EIS is correct, no change to the text was made.

Comment Number 0023.07

Geosafe

Comment Implementability: 1st bullet, The degree of uncertainty of the ISV alternative will be significantly reduced by using smaller ISV units as discussed above.

Response The concept of treating tank waste with large-volume melts may have more technical issues associated with the implementability of the ISV alternative. The configuration proposed in Comment number 0023.01 is smaller in size than the facility depicted in the EIS. This is one of a number of areas where further detailed study potentially could result in an improved process with fewer issues regarding technical implementability. In these areas of potential improvement, the configuration selected for inclusion into the EIS represented a bounding condition, which would result in environmental impacts that were likewise bounding.

Comment Number 0023.08

Geosafe

Comment Implementability: 2nd bullet, We agree that substantial research and development activities would be required to implement the 160 MW ISV system and for this reason have recommended using smaller ISV units closer to the scale of our commercial 4 MW system. Geosafe has already proposed a concept to DOE for treating the single shell and double shell storage tanks using our 4 MW ISV system (see attached white paper dated December 1995). The 60 ft depth limitation for processing the large volume tanks can be reduced by implementing the techniques discussed in comment A 3. [Comment number 0023.03]

Response Alternative configurations for the power supply facility for ISV are possible. The configuration proposed in the comment is smaller than the facility depicted in the EIS. It should not be inferred that the use of a smaller power supply is a feature of any particular vendor or that the use of a smaller power supply constitutes an endorsement by DOE or Ecology. Because a smaller power supply facility would potentially melt only a portion of a tank and its contents, a solution to this problem would have to be formulated before the smaller power supply facility could be considered to be practicable, and substantial research, development, and demonstration activities still would be required. There are a number of areas where further detailed study potentially could result in an improved process. In these areas of potential improvement, the configuration selected for inclusion into the EIS represented a bounding condition, which would result in environmental impacts presented to the decision makers as bounding. The EIS analysis bounds the information suggested by the commentor. For a discussion of the technique of reducing the depths of the tanks, please refer to Comment number 0023.03. Because the information contained in the Draft EIS is correct, no change to the text was made.

Comment Number 0023.09

Geosafe

Comment Implementability: 3rd, bullet, The possibility of an uncontrolled reaction occurring in a tank is mainly limited to 38 tanks containing organics or ferrocyanide material. The DOE Radioactive Tank Waste Remediation Focus Area is currently evaluating the explosive issue concern. Potentially, ISV treatability testing will be required to fully address this concern.

Response Further treatability testing will be required to fully address the concern of uncontrolled reactions in the tanks if the contents were vitrified. There may be answers to the situation that are inherent with ISV, which is that extensive mixing of contents of different tanks to mitigate potential uncontrolled reactions is not included in the process. At present, the testing of the heating of tank contents has been limited, and it may be premature to state that the problem is mainly limited to 38 tanks containing organics or ferrocyanide material. Until further investigations have been completed, DOE and Ecology believe that the statement in the EIS that further analysis is required remains correct. Because the information contained in the Draft EIS is correct, no change to the text was made.

Comment Number 0023.10

Geosafe

Comment Implementability: 4th bullet, We agree that the tank farm containment facility is highly conceptual and recommend that it be scaled down in size from the proposed 500 ft wide by 600 ft long facility to an approximately 120 ft square facility which covers only one tank. The technical difficulties of constructing the smaller facility are minimal.

Response The large tank farm confinement facility is highly conceptual in nature. The area discussed at this point is that further development would be required before any confinement facility, regardless of size, would be expected to comply with current DOE facility design requirements. A confinement facility that is 120 feet on a side is still sufficiently large that additional design study would be required. The technical difficulties that may be expected in designing and constructing the smaller confinement facility would be less than those expected in designing and constructing a much larger confinement facility. It may be optimistic to state that these technical difficulties would be minimal. This is one of a number of areas where further study potentially could result in a process with fewer issues regarding technical implementability. In these areas, the configuration selected for inclusion into the EIS represented a bounding condition, which would result in environmental impacts that were likewise bounding. These bounding impacts are those presented to the decision makers. The EIS bounds the information suggested in the comment. Please refer to the response to Comment number 0023.01 regarding the use of smaller ISV units.

Comment Number 0023.11

Geosafe

Comment Implementability: 5th bullet, The use of a smaller tank containment facility will eliminate most of the construction difficulties. Using a smaller mobile containment facility will allow construction activities to take place in a clean area, thereby eliminating the risks and added expense of working in or around a tank farm exclusion zone.

Response The large tank farm confinement facility may be more difficult to construct. The area being discussed in the EIS at this point is the atypical nature of the design of the large confinement facility and restrictions associated with working in and around the tank farms. While a smaller confinement facility could be constructed adjacent to the tank farms and then moved into position to assume that this will eliminate the risks and added expense of working around the tank farms would be considered premature. This is one of several areas where additional design study potentially could result in process improvements and potentially could result in a process with fewer issues regarding technical implementability. In these areas, the configuration used in the EIS represented a bounding condition, resulting in environmental impacts that also were bounding. Please refer to the response to Comment number 0023.01 regarding the use of smaller ISV units.

Comment Number 0023.12

Geosafe

Comment Implementability: 6th bullet, Inspection of the final waste form can be done by core drilling through the vitrified monolith after a period of cooling. Core drilling is routinely performed on commercial ISV projects to verify waste treatment for project closure. In the past, core drilling has been used to sample untreated tank wastes and should be easily adaptable to sampling a vitrified waste form which is easier to handle. Secondary wastes generated from the drilling can be recycled to future melts. If a core sample fails to meet waste acceptance testing, the area from which it was taken can be retreated by ISV.

Response Methods exist for the sampling of the in situ vitrified product. Many cores would likely be necessary for each tank and the cuttings from the core would require special handling and disposal. While the secondary wastes generated can be returned to the untreated tanks, other problems may be encountered during the development and operating phases of the core drilling system. The core drilling of vitrified HLW is an area that would require additional research and development to investigate further and determine its workability. If core drilling becomes an accepted technique for determining the acceptability of the waste form, the design of the confinement facility would include provision for equipment to accomplish the core drilling. Inspection and potential pretreatment of the final waste form are implementability problems that remain to be solved.

Comment Number 0023.13

Geosafe

Comment Implementability: 7th bullet, Use of the proposed smaller tank confinement facilities will be significantly reduce decontamination and decommissioning problems.

Response The large tank farm confinement facility may be difficult to decontaminate and decommission and these difficulties should be fewer for a smaller facility. Further study could result in an improved process. The information requested in the comment is a level of detail that DOE and Ecology believe is not necessary for meaningful discrimination among the alternatives.

Comment Number 0023.14

Geosafe

Comment B-53, 3rd par., last sent., A reference should be provided for the current research which is addressing depth-enhancement techniques.

Response A reference has been added to the last sentence of the referenced paragraph in Volume Two, Appendix B.

Comment Number 0023.15

Geosafe

Comment B-53, 4th par., Elimination of interstitial spaces between soil particles is not the only mechanism for volume reduction. During ISV treatment a significant volume of tank wastes will be vaporized due to the decomposition of nitrates, nitrites, carbonates and sulfates. This will result in a volume reduction that is expected to exceed 50 percent by volume. In addition, the ISV process will not produce significant quantities of No_x that require special off-gas treatment. The high operating temperature of the ISV melt and its reducing environment will decompose nitrate and nitrite into N_2 and O_2 gas.

Response Elimination of interstitial spaces between soil particles is not the only mechanism for volume reduction. A reduction in volume due to decomposition of the tank wastes will occur. However, at this time, no ISV facilities have been designed for use at the Hanford Site. Until design and testing have been completed, to consider that the ISV process will not produce significant quantities of nitrogen oxides requiring special off-gas treatment is premature. ISV most closely resembles a batch process, where the nature of the reacting materials and the reaction products change as a function of time. Temperature also changes with time during ISV, starting with the cool tank wastes and glass formers and ending with molten glass at a very high temperature. Therefore, while extremely high temperatures will enhance the dissociation of nitrate and nitrate, nitrogen oxides will be produced until those temperatures are reached, and the off-gas treatment system must be able to treat all of the vapors evolved. The information requested in the comment is a level of detail that DOE and Ecology believe is not necessary for meaningful discrimination among the alternatives.

Comment Number 0023.16

Geosafe

Comment B-56, Figure B3.4.3., The NO_2 burner is configured as a lime spray dryer.

Response The essential function of the nitrogen oxide burner is correctly depicted on the flow diagram in Volume Two, Appendix B. The streams entering and leaving the unit are shown correctly. Because the essential function of the unit has been depicted, no changes to the EIS have been made.

Comment Number 0023.17

Geosafe

Comment B-57, 1st par., Treating the area between the tanks unfairly increases the cost of the ISV alternative and should not be included unless other alternatives address this concern. Potentially, an ISV option could be included which addresses the treatment of contamination below and around the tanks.

Response The inclusion of extra material in the zone of vitrified material is unique to the ISV alternative. Treating the area between the tanks would occur as a consequence of the nature of the ISV process, and doing so would not unfairly increase the cost of the ISV alternative. Because of the in situ nature of the process, ISV must have a vitrified zone that extends beyond the tank dimensions to ensure that the tank and its contents have been vitrified. This zone would not exist for the ex situ alternatives, for which retrieval activities will be performed that would be bounded by the tank walls. Because of the technical uncertainty in determining the dimensions of the zone of vitrified material during the melting operation, the preparers of the engineering data package (WHC 1995f) made the assumption to extend the dimensions of the vitrified zone beyond the tank dimensions to include the extent of the tank farms. Using this assumption ensured that the preconceptual costs, energy consumptions, and glass former usages were reasonable. For use in the EIS, these conservative assumptions and resulting calculations form a bounding condition. The use of this bounding condition will result in environmental impacts that are likewise bounding. NEPA requires that bounding conditions be equally compared for the environmental impacts that potentially may result from all alternatives evaluated. Please refer to the response to Comment numbers 0023.01 and 0001.01 for other discussions of subsurface barriers.

Comment Number 0023.18

Geosafe

Comment B-63, last par., The ISV flow diagram (Figure B.3.4.3) does not show a water quench system, venturi scrubber, solids separator, chiller or mist eliminator, which are the standard ISV off-gas treatment system components.

Response Figure B.3.4.3 depicts the major features of the ISV process. At the point when further engineering design potentially would be done, an expanded set of process flow diagrams would be developed. Because the description of the process in Section 3.4.3 of Appendix B refers to the water quench, scrubber, solids separator, chiller, and mist eliminator, no changes to the EIS have been made. These treatment systems were included in the design for the process, but were considered too much detail for presentation in the EIS. The information requested in the comment is a level of detail that DOE and Ecology believe is not necessary for meaningful discrimination among the alternatives.

Comment Number 0023.19

Geosafe

Comment B-64, 3rd par., The degree to which organics and ferrocyanides present an explosive issue in the tanks is presently unknown and is currently being researched by DOE. At most an estimated 38 tanks potentially contain high enough concentrations of these contaminants to be of concern (PNL 10773).

Response The degree to which organics and ferrocyanides present an explosive issue currently is under investigation. There may be answers to the situation that are inherent with ISV, which is that extensive mixing of the contents of different tanks to mitigate potential uncontrolled reactions is not included in the process. At present, the testing of the heating of tank contents has been limited, and it may be premature to state that the problem mainly is limited to 38 tanks of organics or ferrocyanide material. Until further investigations have been completed, the statement in the EIS that safely treating reactive materials requires further analysis is correct. Because the information contained in the Draft EIS is correct, no change to the text was made.

Comment Number 0023.20

Geosafe

Comment 1st bullet, Geosafe agrees that the proposed ISV alternative is more conceptual in design than the ex situ vitrification alternative but has made the following recommendations to significantly decrease the degree of uncertainty associated with cost, schedule and resource requirements.

- Use smaller ISV equipment and multiple melts to treat tanks
- Use a smaller moveable tank containment building
- Reduce tank effective height to lower treatment depth and volume.

Response Additional areas for further research and investigation associated with ISV are possible. Using smaller ISV equipment and multiple melts, smaller, moveable confinement facility, and tank overburden to fill voids and lowering the tank dome into the tank are areas where further investigation may be valuable. The configuration selected for inclusion into the EIS represented a bounding condition, which would result in environmental impacts that also were bounding. These bounding impacts were presented to the decision makers. Please refer to the response to Comment numbers 0023.01, 0023.03, and 0023.11. Because the information contained in the Draft EIS is correct, no change to the text was made.

Comment Number 0023.21

Geosafe

Comment 2nd bullet, The degree of uncertainty for the ISV alternative can be reduced by using smaller equipment which is considered highly feasible given the current understanding of the technology.

Response Alternative configurations for the tank farm confinement facility for ISV are possible. The configuration proposed in Comment number 0023.01 includes a confinement facility that is 120 feet on a side. The area under discussion in the EIS is the higher degree of uncertainty for the exact equipment required for ISV versus ex situ alternatives. The 120-foot confinement facility is still several times larger than that used in current development work for ISV. To state that this configuration is highly feasible could be considered premature. Comment number 0023.01 discusses concerns related to the movement of a smaller confinement facility and its off-gas facilities. Because these concerns remain as issues and problems to be resolved, the EIS is correct in referring to the degree of uncertainty involved. Because the information contained in the Draft EIS is correct, no change to the text was made.

Comment Number 0023.22

Geosafe

Comment 3rd bullet, Implementing the recommendation to use a smaller containment facility will eliminate all these concerns except for the need to characterize the tanks. Tank waste characterization is a generic concern that is applicable to all treatment alternatives and is not limited to the ISV alternative.

Response Vitrifying one tank at a time will not require the characterization of an entire tank farm if a smaller, mobile confinement facility were to be used. ISV by its very nature does not retrieve the tank contents. Consequently, there is no opportunity to advantageously blend the tank contents, as would be the case if several tanks were retrieved at the same time as in the ex situ alternatives. To consider the smaller confinement facility will eliminate all these concerns except the need to characterize the tanks would be premature. Still, ISV is basically a batch process (or potentially a semi-continuous process). One characteristic of a batch process is the changing nature of the reactants and products as a function of time. The system must be able to process the expected products, and this requirement does not change with the size of the confinement facility. Further detailed study would result in an improved process; however, no changes to the information presented in the EIS are required. Please refer to the response to Comment number 0023.01.

Comment Number 0023.23

Geosafe

Comment 4th bullet, An estimated 20 tanks potentially contain organics at concentrations that may represent an explosive concern. Research on treating these problem tanks could be conducted while other non-effected tanks are being processed.

Response The degree to which organics present an explosive issue is currently under investigation. Extensive mixing of waste from different tanks to mitigate potential uncontrolled reactions is not included in the process. At present, the testing of the heating of tank contents has been very limited, and it may be premature to state that the problem mainly is limited to 20 tanks containing organics. Concurrent research and testing on treating these problem tanks could be conducted while other non-affected tanks are being processed. This research must be successfully completed before this method could be used to remediate tanks that may present an explosive concern. Until further investigations have been completed, the statement in the EIS that the safety of drying some waste types is uncertain remains correct, and as a result, no changes to the EIS have been made. The potential for fires and explosions in the tanks is addressed in Volume One, Section 5.12 and Volume Four, Appendix E. Because the information contained in the Draft EIS is correct, no change to the text was made.

Comment Number 0023.24

Geosafe

Comment 5th bullet, Geosafe recommends using smaller ISV units which should significantly reduce the uncertainties associated with off-gas treatment. The high operating temperature of ISV has been demonstrated to effectively decompose nitrogen compounds without the formation of NO_xS and greatly reduces off-gas treatment concerns. The calcium sulfate waste stream should not be recycled because the sulfates will be reintroduced back into the off-gas.

Response There is the potential for the production of a secondary waste stream of potentially contaminated calcium sulfate from ISV. This waste stream should not be recycled because the sulfates may not be incorporated into the melt and may be reintroduced into the off-gas. However, at this time, no ISV facilities have been designed for use at the Hanford Site and none have been designed of the size needed to vitrify the tank waste anywhere in the world. Numerous ISV facilities have had problems with off-gas treatment and fires. Until development work has been completed, to state that the high operating temperature of the ISV process would effectively decompose nitrogen compounds without the formation of nitrogen oxides and greatly reduce off-gas treatment concerns would be considered premature. ISV most closely resembles a batch process, where the nature of the reacting materials and the reaction products change as a function of time. Temperature changes also occur with time during ISV, starting with the cool tank wastes and glass formers and ending with molten glass at a very high temperature. So while extremely high temperatures will enhance the dissociation of nitrate and nitrate, nitrogen oxides will be produced until those temperatures are reached. The off-gas treatment system must be able to treat all of the vapors that are evolved. Because these uncertainties will remain regardless of the size of the ISV units, no changes to the EIS have been made. Please also refer to the response to Comment number 0023.01 for a discussion of smaller ISV units.

Comment Number 0023.25

Geosafe

Comment 6th bullet, The 60 ft depth limitation is overly conservative and can be reduced by removing overburden from the tanks and lowering the effective height of the tank as discussed in comment A 3. [Comment number 0023.03]

Response Please refer to the response to Comment numbers 0023.03 and 0023.08.

Comment Number 0023.26

Geosafe

Comment 7th bullet, The use of the proposed smaller tank containment facility (120 ft by 120 ft) will eliminate structural design and costing uncertainties.

Response The EIS addresses only the uncertainty that remains in the design of the large (i.e., 500- by 600-foot) confinement facility. At this time, no ISV facilities have been designed for use at the Hanford Site. Until additional technology development has been completed, it would be considered premature to state that the use of the smaller confinement facility will eliminate structural design and costing uncertainties. The information requested in the comment is a level of detail that DOE and Ecology believe is not necessary for meaningful discrimination among the alternatives.

Comment Number 0023.27

Geosafe

Comment 8th bullet, Verification of the ISV monolith can be performed by core sampling which is a well demonstrated technology. Allowances will have to be made for coring of a radioactive glass monolith but it is feasible given an enclosed system and sufficient concern for safety issues. Secondary wastes generated from coring can be directly recycled to future melts thus eliminating waste disposal concerns.

Response DOE and Ecology agree with the comment that methods exist for the sampling of the in situ vitrified product. The core drilling of vitrified HLW is an area that would require additional research and development to determine its workability. If core drilling becomes an accepted technique for determining the acceptability of the waste form, the design of the confinement facility would include provision for equipment to accomplish the core drilling. While the comment is correct in stating that the secondary wastes generated can be returned to the untreated tanks, it is possible that other problems will be encountered during the development and operating phases of the core drilling system. The text referred to in the comment discusses the fact that inspection and potential pretreatment of the final waste form are problems of implementability that remain to be solved. Despite the fact that methods are available for sampling the vitrified waste form, the technical problems associated with this issue remain to be solved. The information requested in the comment is a level of detail that DOE and Ecology believe is not necessary for meaningful discrimination among the alternatives.

Comment Number 0023.28

Geosafe

Comment 9th bullet, The use of the smaller ISV system will eliminate concerns regarding movement of the off-gas system.

Response The EIS addresses the uncertainty that remains in the design of the off-gas treatment facilities. Until additional technology development has been completed, to state that the use of the smaller ISV system will eliminate concerns regarding movement of the off-gas system would be considered premature. Please refer to the response to Comment number 0023.24. The information requested in the comment is a level of detail that DOE and Ecology believe is not necessary for meaningful discrimination among the alternatives.

Comment Number 0023.29

Geosafe

Comment 10th bullet, The use of a smaller ISV system will greatly reduce the time needed to retreat a specific area in a tank if it fails to meet the treatment criteria.

Response The EIS addresses the uncertainty that would occur in the operations schedule if an area as large as a complete tank has to be retreated as a result of unsuccessful ISV. Until additional technology development has been completed, to state that the use of the smaller ISV system will greatly reduce the time needed to retreat a specific area in a tank if it fails to meet the treatment criteria would be considered premature. The time required to retreat a tank is not a function of the size of the confinement facility. The information requested in the comment is a level of detail that DOE and Ecology believe is not necessary for meaningful discrimination among the alternatives.

Comment Number 0023.30

Geosafe

Comment 11th bullet, The concern of mixing fluxants into deep zones of the tank can be reduced by implementing the treatment depth reduction techniques recommended in comment A 3 (See Comment number 0023.03). Geosafe has already demonstrated the mixing of fluxants at full scale with excellent results.

Response Thermal mixing is well known in conventional electric furnaces and should work well for ISV. Because thermal mixing in electric furnaces is a natural phenomena, its presence does not constitute an endorsement of the application of a particular technique or equipment. The statement in the EIS refers to further development work that may be required. The information requested in the comment is a level of detail that DOE and Ecology believe is not necessary for meaningful discrimination among the alternatives.

Comment Number 0072.97

CTUIR

Comment P 3-48: Sect. 3.4.5: In Situ Vitrification Alternative: this section does not adequately discuss how all of the vitrified ground and waste is to be verified for vitrification, and how this verification process will include leakage, migration, below the area of impact. This process has not been adequately explained for the purposes of this EIS.

Response Further technology development regarding the implementation of the ISV alternative may be required. Volume One, Section 3.4.5.7 and Volume Two, Section B.3.4.4 discuss the issues applicable to the implementability of this alternative including inspection of the final waste form to confirm that all of the waste is stabilized and the waste form is acceptable. One possible method of verification would be drilling through the vitrified mass to ensure that vitrification was complete, but these drill holes would not necessarily confirm any potential migration that may exist below the vitrified mass. Migration in the vicinity of the vitrified mass could be verified by drilling additional boreholes near each tank farm when ISV had been completed. Please refer to a related discussion on verification in the response to Comment number 0023.12.

Comment Number 0072.98

CTUIR

Comment P 3-54: Sect. 3.4.5.7: Implementability: How is excess melting going to be addressed, Please describe the fractionation process of the melt? What are the anticipated cooling times, and how have these times been calculated, are they based on the fractionation process? If the times are not based on the fractionation process what exactly are they based on? What is the verification process for the vitrification, the fractionation, the cooling, the immobilization?

Response Many crucial questions must be answered before the ISV alternative can be implemented. Volume One, Section 3.4.5.7 contains discussions of the substantial research, development, and demonstration activities that would be required. Inspection of the final waste form to confirm stabilization of the waste is one area requiring more information. The implementability of this alternative is not known at this time. To account for these uncertainties, additional technology development time and costs were incorporated into the analysis of these alternatives. The information requested is a level of detail that DOE and Ecology believe is not necessary for meaningful discrimination among the alternatives. Implementability was one factor analyzed for the technologies included in the alternatives analysis.

Comment Number 0072.99

CTUIR

Comment P 3-54: The technical uncertainties associated with this process are just as great for the MUSTs because the contents of the MUSTs have been inadequately described within this EIS.

Response As is explained in Volume Two, Section A.2.3, definitive characterization data do not currently exist for the inactive MUSTs. Because they received the same waste products that are contained in the tanks, the concentration of constituents is expected to be approximately the same. Volume Two Table A.2.3.1 lists the current estimated waste volumes for the MUSTs and briefly comments on the use of each tank. ISV of the small MUSTs may present less of a technical challenge because the size of the melt more closely conforms with previously demonstrated vitrification processes. Please refer to the response to Comment numbers 0012.14, 0072.169, 0029.01, and 0060.02 for a discussion related to MUST contents.

Comment Number 0072.185

CTUIR

Comment P B-53: Sect. B.3.4: Same comment as above. [Please refer to the response to Comment number 0072.195.]

Response Please refer to the response to Comment number 0072.195.

Comment Number 0102.01

Eister, Warren

Comment The Draft Environmental Impact Statement for the Hanford Site Tank Waste Remediation System -

Summary (DOE/EIS-0189D) seems to suggest the choice system would be In Situ Vitrification (Figure S.6.2 along with Tables S.7.2 and S.7.3).

It is very reassuring that decisions made more than twenty years ago continue to be re-evaluated. Unfortunately those decisions have been extremely difficult to implement.

However, in spite of the continuing unresolved difficulties, this EIS Summary reports that DOE has already adopted the Phased Implementation System which is dependent on potential geologic repositories and involves extensive process and transportation activities.

Is the In Situ Vitrification technology being developed with the same level of effort as the Phased Implementation?

Would this In Situ Vitrification System be applicable to the:

- Savannah River site?
- Spent fuel from the nuclear power reactor program?
- TRU waste?
- Low-level wastes?

Are there other technologies being sought that would allow the spent fuel from the nuclear power program to remain in the vicinities of the current power plant sites?

Response The preferred alternative for tank waste identified in the Draft EIS and Final EIS is Phased Implementation not ISV. DOE and Ecology acknowledge the preference expressed in the comment and will take this preference and other public comments into consideration when making a final decision on remediating the TWRS waste. Please refer to the response to Comment number 0072.05 regarding NEPA requirements for the analysis of alternatives and Comment numbers 0055.03 and 0005.07 for a discussion of the role of the EIS in the decision making process. Repository costs and uncertainties analysis results for each alternative have been included in Volume Two, Appendix B and Volume Five, Appendix K, respectively, in the Final EIS.

The TWRS EIS focused on tank waste remediation alternatives. Technology evaluation was limited to those technologies currently available or for which sufficient development information was available. DOE is not currently developing any remedial technologies. Potentially-applicable ISV technologies are under commercial development. Technologies development and/or evaluation would be conducted during the detailed design and demonstration phases of the preferred alternative. Issues related to ISV technology applicability at other DOE sites, for commercial nuclear power programs, or to other radioactive waste types beyond those required for the alternatives evaluation were not considered because they are beyond the scope of the EIS.

Please refer to the response to Comment number 0037.03 for more information concerning interim onsite storage of HLW and compliance issues related to the Nuclear Waste Policy Act.

L.3.4.7 Ex Situ Intermediate Separations Alternative

Comment Number 0005.45

Swanson, John L.

Comment Page 3-59 contains a sentence regarding the Tri-Party Agreement requiring the retrieval function to remove waste to an extent based on volume or as much as is technically possible, WHICHEVER IS LESS. I believe you mean to say remove the MOST, leaving the LEAST - but that is not what the sentence says.

Response The cited text has been revised as follows, "The Tri-Party Agreement (i.e., Milestone M- 45-00) requires that the removal function remove waste to the extent that SST waste residuals meet specific volume requirements based on tank type, or that as much waste is removed as technically possible, whichever action results in the least residual waste volume" (Ecology et al. 1994).

Comment Number 0005.46

Swanson, John L.

Comment Page 3-67 defines an off-gas stream from a vitrifier as a "gaseous air stream containing combustion gases." This is true for a combustion-fired melter, but how about a joule-heated melter?

Response Volume One, Section 3.4.6.2 states that fuel-fixed melters have been included for analysis in the EIS. It is further stated that future evolution may result in another melter configuration. With either the joule-heated or fuel-fixed melter, a large quantity of off-gas with contaminants such as SO_x and NO_x must be treated. The total volume of gas with a fuel-fixed melter would be greater with the use of kerosene and oxygen for the fuel, but the total amounts of SO_x and NO_x would not differ greatly. The fuel-fired melters considered provide a more conservative analysis in the design and treatment of the off-gas for discharge to the environment. Please refer to the response to Comment numbers 0005.42, 0072.91, 0023.01, 0023.15, 0023.24, 0023.28, and 0072.101 for discussions of issues related to off-gassing. Because the information contained in the Draft EIS is correct, no change to the text was made.

Comment Number 0005.47

Swanson, John L.

Comment Page 3-67, last paragraph of 3.4.6.2 ("Driving heavy equipment--") seems to be out of place. This same paragraph appears in similar locations for other alternatives too; the same comment applies in those sections as well.

Response Because this is an issue common to many of the alternatives, a better location for a one-time entry to the section has been determined. This discussion on mitigating a potential accident has been moved to a discussion of elements common to the alternatives in Volume One, Section 3.4 and Volume Two, Appendix B. This statement of concern appears on several pages within Volume One, Section 3.0 and Volume Two, Appendix B.

Comment Number 0027.10

Roecker, John H.

Comment Technical Uncertainty

To state that the technical uncertainty of the intermediate and extensive separations alternatives are both moderate is erroneous and misleading to those who are not familiar with the technologies involved. Intermediate separations requires three technologies, all of which have been demonstrated, while extensive separations requires at least ten, most of which have not been demonstrated. This misleading information needs to be corrected.

Response The degree of technical uncertainty provided in the Summary assigns a high, medium, or low ranking for the entire remediation alternative. DOE and Ecology acknowledge that there is a higher level of technical uncertainty with extensive separations than with intermediate separations. However, overall, both alternatives fall into the moderate category. Additional discussion regarding technical uncertainty is provided in Volume One, Section 3.4 and Volume Two, Appendix B and the response to Comment number 0005.03.

Comment Number 0036.16

HEAL

Comment The EIS states that intermediate separations would reduce the waste going to the repository. It adds, "The other goal of separations would be to limit the generation of additional waste during the separations processes" (p. 3-65). What does this passage mean?

Response Limiting the generation of additional waste during the separations process means that design and implementation of the HLW/LAW separations processes would consider the volume of LAW along with the volume of

HLW that would be generated. One means of accomplishing this would be to limit the introduction of sodium hydroxide during the enhanced sludge washing process, which would limit the overall amount of sodium in the resulting LAW form.

Comment Number 0057.03

Garfield, John

Comment With respect to primarily the cost, the EIS references the document from '94 Boomer et al. That document compares two alternatives that are nearly identical to intermediate separations, then extensive separations is called clean and enhanced sludge washing in that document. It shows a cost penalty for using clean of $7 billion dollars compared to enhanced sludge washing. Those same alternatives show a $3 billion dollar advantage in the Environmental Impact Statement Draft. That is a $10 billion dollar swing. That deserves investigation. The repository comments convey part of that. The rest relates back to my earlier remarks about the headquarters influence.

Response The cost estimates were reviewed and revised for the Final EIS. The waste loading and blending assumptions that impact the volume of HLW have been revised to reflect the recommendations of an independent technical review team. The size of the HLW canisters has been revised to reflect recent DOE-RW findings that a longer canister for Hanford HLW is technically feasible. These changes, as well as the resulting cost impacts, were revised and are included in Volume One, Section 3.4 and Volume Two, Appendix B. For more information on issues relating to HLW canisters and repository costs, please refer to the response to Comment numbers 0081.02 and 0008.01.

Comment Number 0057.05

Garfield, John

Comment The next comment I would like to make is that the chosen case built around the extensive sep..or excuse me the intermediate separations data of without repository cost shows it $30 billion dollars. That estimate assumes a stand-alone high-level waste treatment facility which would cost in the vicinity of $1 to $2 billion dollars and add another equivalent amount in operating costs. There is some recent data developed using a single facility but which can be - its mission can be modified both in terms of scope and capacity to accommodate both low-level treatment at a smaller scale through the 200-ton per day capacity 1 to 200-ton per day capacity for the full scale low-level treatment and then can be converted for high-level treatment. That is the only sane approach to this problem. Building three demonstration plants and two full-scale plants is a lunacy that will cost us $30 billion dollars. A simpler facility approach that I just described would cut those costs in approximately half and, in fact, the studies release from the DOE reading room suggests that cost is about $16 to $18 billion dollars. That should be the basis for the EIS intermediate separations case.

Response DOE and Ecology recognize that there are opportunities for optimizing the costs estimated for each of the alternatives addressed in the EIS. As discussed in the EIS, the alternatives were developed to bound the impacts associated with remediating the tank waste. Process and facility design optimization would not be precluded with the selection of any of the alternatives presented in the EIS. For more information on the topic, please refer to response to the Comment number 0072.05.

The Draft EIS addressed the full range of reasonable alternatives. The alternative identified is bounded by the alternatives addressed in the Draft EIS, and DOE and Ecology believe that including the requested alternative would not provide valuable additional information to the public or decision makers.

Comment Number 0072.100

CTUIR

Comment P 3-56: Sect. 3.4.6: Ex Situ Intermediate Separations Alternative: The separation of the Waste streams into HLW and low activity waste seems confusing. Low activity waste is waste that is a subset of HLW? What are the legal requirements for classifying waste as LAW? Have the Affected Tribes been consulted regarding this?

Response LAW is the waste remaining after removal of as much of the radioactivity from HLW as practicable. The definition of LAW is provided in Volume One, Section 1.0. DOE and the NRC have had formal discussions on tank waste classification and LAW regulation; however, DOE would need to formally solicit an opinion from the NRC regarding the classification of LAW. Volume One, Section 6.2 provides additional information on tank waste classification and the results of the discussions between DOE and the NRC. Criteria must be formalized as to the extent to which the HLW in the tanks must be separated for the residual waste to meet requirements for incidental waste, LAW, as well as the DOE and Washington State definitions of LLW and hazardous waste requirements of the State of Washington. Design specifications for HLW and LAW treatment will require that waste forms meet applicable criteria for disposal in the potential geologic repository or as LAW for onsite disposal, respectively.

DOE plans for onsite near-surface disposal of LAW date back to the 1988 Hanford Defense Waste EIS ROD (DOE 1987). That NEPA process, as well as subsequent consideration of onsite disposal of LAW during the 1989 and 1994 Tri-Party Agreement negotiations, and the Tank Waste Task Force process (HWTF 1993), provided interested parties as well as Tribal Nations with the opportunity to comment on the planned onsite disposal of LAW. The TWRS EIS and the public involvement process for Tri-Party Agreement amendments associated with the privatization initiative provided additional opportunities for Tribal Nation input into the decision-making process related to this issue. The Tribal Nation consultation process is discussed in the response to Comment number 0072.149.

Comment Number 0072.101

CTUIR

Comment P 3-56: PP 3: The LAW is to be quenched into a 'cullet', this indicates that there is going to be an additional secondary waste stream generated from the reaction of molten silicates, nitrates, hydroxides, oxides, metals and water. What will be done with this waste stream. Will this waste stream be classified as High level liquid waste? The off gasses that are produced are supposedly going to be treated in some fashion, please explain how this is to be accomplished including feed rates, volume of off gas produced, filter failure rates, retrievable useable material, and indicate where this process has been proven including references.

Response The technical data that served as a basis for developing the Ex Situ Intermediate Separations alternative are referenced in the EIS (WHC 1995 n, j, i and Jacobs 1996) and are available for review as part of the TWRS EIS Administrative Record and in DOE Reading Rooms and Information Repositories.

Quench water is a secondary waste stream that would contain contaminants as a result of quenching the molten LAW glass in order to produce the cullet. This quench water would be recycled extensively either as quench water or back to the front of the process to be added to the LAW stream for vitrification. This liquid waste stream would not be expected to be classified as HLW.

The amount of secondary waste generated during operations of the Ex Situ Intermediate Separations alternative would consist primarily of off-gas and liquid effluent emissions identified in Volume Two, Table B.11.05. The off-gas and liquid effluents would be treated to remove contaminants to the maximum extent possible before being discharged. The HLW vitrification process would result in gas flows out the stack of approximately 3,500,000 metric tons (mt) over the life of the facility. The radiological and chemical concentrations to be released from the stack were calculated and used in the routine risk assessment. The liquid effluent from the HLW vitrification facility was estimated to be 1,200,000 mt (before recycle) based on material balance calculations. Volume Two, Section B.3 describes the liquid effluent processing of secondary radioactive waste streams for all alternatives. In addition to these emissions, secondary waste consisting of contaminated filters and spent ion exchange resins would be generated during treatment operations.

The generation of off-gas during the vitrification process would result from the evaporation of water, thermal destruction of chemical compounds, evolution of volatile compounds, and the entrainment of particulates in the off-gas stream. A detailed description of the off-gas system is provided in Volume Two, Section B.3. Control technologies that would be employed to reduce emissions include: quench towers, venturi scrubbers, chillers, demisters, high-efficiency particulate air (HEPA) filtration, sulfur recovery, and NO_x destruction. The off-gas emissions from the vitrification plants are included in the risk assessment. The off-gas treatment processes that would be used are the same technologies that have been successfully used in commercial and defense nuclear industry as well as the chemical processing industry.

Comment Number 0072.102

CTUIR

Comment P 3-56: PP 5: What is the amount of secondary waste generated from this process? Will there be material that can be recycled? Will the secondary waste stream have to be reprocessed for additional radionuclide removal?

Response Secondary waste streams will include treatment for removal of radionuclide and chemical contaminants to the maximum extent possible before discharge. Off-gas streams will include various technologies to treat chemical and radionuclide emissions during operations. Liquid effluents would be collected and sent to the onsite Liquid Effluent Treatment Facility for treatment. Please refer to the response to Comment numbers 0072.101 and 0072.109.

Comment Number 0072.103

CTUIR

Comment P 3-59: top of the page: Where does the strontium end up with this process, in the liquid or the solids phase?

Response The strontium will be mainly in the HLW solid phase during the enhanced sludge washing process used for the Ex Situ Intermediate Separations alternative. A small amount, approximately 6 percent of the strontium and decay product activity, would end up in the LAW.

Comment Number 0072.104

CTUIR

Comment P 3-59: Sect. 3.4.6.2: What was the process for determining the average feed stream, and what are the expected ranges for this feed stock in relation to the glass content and characteristics? What will be the process for determining what to do, in the case of 'out of operating' mode? Will this process entail stocking waste from the other tanks in order to blend the feed mixture? If this is the case, has this information been costed out to show how many and how large these out of ground tanks will be?

Response The technical data that served as a basis for developing the Ex Situ Intermediate Separations alternative is referenced in the EIS (WHC 1995i, j, n and Jacobs 1996) and available for review as part of the TWRS EIS Administrative Record and in DOE Reading Rooms and Information Repositories. Additional details regarding the facility layout, including the melter feed system and associated tankage, are provided in Volume Two, Section B.3.

The average feedstream was developed by taking the average overall chemical and radiological inventory including dilution water that would be added during waste retrieval operations. The material balance calculations assumed that the tank waste would be adjusted to 5 molar soluble sodium during retrieval and transfer. It is expected that there will be some variation in the feed stream composition during the waste treatment process. Compositional limits for waste feed would be established during the detail design phase and would take into consideration the affect of variability in the waste feed on the vitrification process, the acceptability of the glass, as well as safety concerns. Blending of the waste during retrieval and the ability to sample and blend waste in the lag storage area would minimize the variance in the waste feed. The lag storage and melter feed system would provide further opportunity for waste feed conditioning. The engineering data developed include the necessary equipment and processes to blend the waste feed and no additional out of ground tanks are required.

Comment Number 0072.105

CTUIR

Comment P 3-61: Sect. 3.4.6.2:. PP 3: S 1: The figure 3.4.9, depicts a sluicing module at the end of the end effector. If sluicing has to be discontinued because of tank leakage, please describe this sluicing module, and why it is depicted.

Response The sluicing module referred to in the comment would minimize the amount of water introduced to the tank during retrieval as compared to articulated arm method of sluicing. The articulated arm would be deployed when there was concern about the integrity of the tank or a potential for tank leakage. Other types of engineered modules, such as mechanical end effectors, could be used for selected retrieval operations with the articulated arm. Please refer to the response to Comment number 0029.01 for additional information concerning sluicing.

Comment Number 0072.106

CTUIR

Comment P 3-66: PP 1: S 7: Within this sentence there is a reference that silica is sand. Silica is not sand. Sand can consist of many things, including silicon dioxide.

Response Sand is commonly defined as loose, fine particles of disintegrated rock. The sentence that is referred to in the comment is describing glass formers, some of which may be either silica or sand (depending on the desired composition of the glass).

Comment Number 0072.107

CTUIR

Comment P 3-66 PP 2: S 1: Quenching molten glass will not necessarily make gravel sized pieces, in addition the pieces formed will have a high percentage of fractures, and necessarily a very large surface area, please explain how these cullets are better at resisting aging, and weathering, and where are the references for this process?

Response The treatment facilities that would produce glass cullet as a waste form would have equipment in place to produce uniform-sized cullet. Glass fines would be screened and recycled back to the melter and oversized cullet would pass through a roll crusher to produce cullet of acceptable size for handling. Glass cullet would have a larger surface area-to-volume ratio as compared to monolithic pours of glass (e.g., glass logs) in canisters. This discussion is included in Volume Two, Section B.3 of the EIS. Glass cullet would have higher leach rates than monolithic pours of glass due to the higher surface area-to-volume ratio. The acceptability of HLW glass cullet produced under the Ex Situ No Separations alternative is identified in Volume One, Sections 3.4 and 6.2 and Volume Two,

Appendix B. The increased leaching for cullet was taken into account when the impacts associated with the immobilized LAW were analyzed in the EIS in Volume One, Section 5.2 and Volume Four, Appendix F. Please refer to the response to Comment numbers 0035.04, 0012.11, and 0052.11 for a discussion of waste form and storage issues.

Comment Number 0072.108

CTUIR

Comment P 3-67: PP 2: What does partial recycle of off gas mean? Does this mean that there is going to be a substantial amount of off gas released to the environment? Has this been incorporated into the risk section? Have the impacts of this off gas been assessed as to their affects to Native Americans?

Response Each tank waste alternative that uses high-temperature processing (vitrification or calcination) would make extensive use of recycle streams to recycle back into the treatment process volatile radionuclide and chemical constituents captured in the off-gas system. These recycle streams would minimize the generation of secondary waste. It has been determined that a bleed stream would be required for each alternative to avoid a continuous buildup of certain volatile radionuclides and chemical constituents, namely technetium and mercury, in these recycle streams.

Complete recycle of the more volatile constituents is not possible. The off-gas emissions estimates used for risk assessment were developed considering volatility and the ability of the off-gas treatment system to capture and recycle individual constituents.

Please refer to the response to Comment numbers 0072.207 and 0072.91 for discussions on assessment of Native American risk resulting from routine air emissions during remediation. The Tribal consultation process is discussed in Comment number 0072.149.

Comment Number 0072.109

CTUIR

Comment P 3-68: PP 4: Bottom of the Page: One 22 metric ton per day HLW does not seem like enough, especially since there is going to be down times for change outs, plugging, melt inconsistencies, spills, and other process related problems. Wouldnt it be more prudent to plan for additional melt capacity above and beyond the 20 mt as allowances for capacity needs? Additionally, what is the total amount of secondary waste generated with his process? How will this compare to the global vitrification process already in use in France, and the United Kingdom? What are the expected off gases, and what are the treatment process being proposed? Are these gasses being addressed in the risk portion of this document?

Response The 20 mt (22 ton) melter capacity for HLW vitrification under the Ex Situ Intermediate Separations alternative was calculated using a 60 percent overall operating efficiency along with a 13-year operating duration. The 60 percent overall operating efficiency takes into account down time due to process-related problems.

The amount of secondary waste generated during operations of the Ex Situ Intermediate Separations alternative would consist primarily of off-gas and liquid effluent emissions identified in Volume Two, Section B.11, Tables B.11.05 (radiological) and B.11.06 (nonradiological) The off-gas and liquid effluents would be treated to remove contaminants to the maximum extent possible before being discharged. The HLW vitrification process would result in gas flows out the stack of approximately 230,000 mt over the life of the facility. The radiological and chemical concentrations that would be released from the stack were calculated and used in the routine risk assessment. The liquid effluent from the HLW vitrification facility was estimated to be 72,000 mt based on material balance calculations. Volume Two, Section B.3 describes the liquid effluent processing of secondary radioactive waste streams for all of the alternatives. In addition to these emissions, secondary waste consisting of contaminated filters and spent ion exchange resins would be generated during treatment operations.

A discussion of foreign vitrification technologies can be found in Volume Two, Section B.9. A comparison of secondary waste generation at foreign vitrification facilities was not made; however, the generation of gaseous and liquid effluent streams would be expected to be the same for similar waste types and processing rates. Regulatory requirements for gaseous and liquid discharges would control the number and type of treatment technologies employed to reduce the risks to human health and environment. These requirements would be different in foreign countries. The Hanford Waste Vitrification Plant Foreign Alternatives Feasibility Study indicated that plants operating in foreign countries would require additional process equipment for treating melter off-gas and other effluents to meet United States environmental requirements.

The generation of off-gas during the vitrification process would result from the evaporation of water, thermal destruction of chemical compounds, evolution of volatile compounds, and entrainment of particulates in the off-gas stream. A detailed description of the off-gas system is provided in Volume Two, Section B.3. Control technologies that would be employed to reduce emissions include: quench towers, venturi scrubbers, chillers, demisters, HEPA filtration, sulfur removal, and NO_x destruction. The off-gas emissions from the vitrification plants are included in the risk assessment.

Comment Number 0072.110

CTUIR

Comment P 3-70: Sect. 3.4.6.5: Post Remediation: this section has to be, either removed or changed to reflect the clean closure option. Additionally during closure, the tanks are not supposed to have residual equal to 1 percent but should be less than 1 percent. The MUSTs, pump pits, valve boxes, and diversion boxes, final disposition has not been firmly established within this EIS. If these ancillary equipment are to be dealt with under clean closure conditions then they need further definement in terms of their contents, their extent of contamination and their disposal.

Response Closure is not included in the scope of this EIS because there is insufficient information concerning the amount of contamination to be remediated. However, Volume One, Section 3.3 addresses how tank waste remediation and closure are interrelated because some of the decisions made regarding how to treat and dispose of tank waste may impact future decisions on closure. There are three representative types of closure addressed. These include clean closure, modified closure, and closure as a landfill. The referenced paragraphs are included in Volume One, Section 3.4 to illustrate the type of activities following remediation rather than specifying the type of closure. The value of, "... a residual equal to no more than 1 percent ...," was used to bound the impacts from the tank residuals. Closure of ancillary equipment also is not included in the scope of this EIS. Issues related to tank farm closure are discussed in Comment number 0072.08. Please refer to the response to Comment numbers 0012.14, 0072.50, and 0101.06 for MUST characterization and issues related to closure. Because the analysis requested in the comment is not within the scope of the EIS, no modification to the document is warranted.

Comment Number 0072.111

CTUIR

Comment P3-72: Sect. 3.4.6.7: Implementability: bullets 3,6: If Low Activity Waste has not been thoroughly described, and permitted, how does this EIS propose to deal with the enormous amount of uncertainty involved throughout all the process stages? This is not the easiest way of dealing with the waste. Because the Nuclear Regulatory Commission has not finished with the negotiations, why in Section 3.4.6.5., does it mention that this LAW be buried under the Hanford Barrier? Burying this waste in a cullet form under the Hanford Barrier is the same as saying DOE made the waste, used their contractors to partially treat it, buried it and then walked away leaving the Affected Tribes to deal with the consequences. This is not acceptable. The ex situ intermediate separations alternative therefore is not acceptable. Changes made to this alternative, such as determining the LAW disposal criteria will necessarily need CTUIR input.

Response DOE and Ecology acknowledge the concerns regarding uncertainty expressed in the comment. To develop engineering data required to perform impact analyses for each of the alternatives, assumptions were made regarding the technologies that have been configured to create a remediation alternative, including process stages and waste form. Also, for the purposes of comparing alternatives, a single and consistent method of closure was assumed for all of the alternatives. Closure as a landfill covered by a Hanford Barrier was chosen as the representative closure method for analysis. This does not mean that closure as a landfill is proposed or necessarily would be selected in the future. Please refer to the response to Comment number 0072.08 for more information regarding closure. Although these assumptions were based on best information available, applications of a similar technology, or engineering judgement, there are uncertainties associated with each of the alternatives. Major assumptions and uncertainties are addressed in Volume One, Section 3.4. Additional uncertainty analyses were completed for the Final EIS, and are included in Volume Five, Appendix K.

DOE and Ecology acknowledge the concerns regarding LAW expressed in the comment. LAW is the waste remaining after removal of as much of the radioactivity from HLW as practicable. DOE and the NRC had formal discussions on the way tank waste is classified and how the LAW portion might be regulated in the context of the previously planned grouted LAW. 58 FR 12344, March 1993, states that disposal of residual waste from the DST waste would only be a small fraction of the reprocessing wastes originally generated at the Site; residual waste material should be classified as incidental waste, since they are wastes incidental to the process of recovering HLW; the residual activity of these incidental wastes would be below the concentration limits for Class C wastes under the criteria of 10 CFR part 61; and the disposal of the residual would not be subject to NRC licensing. Section 6.2 provides additional information on tank waste classification, and the results of the discussions between DOE and the NRC. However, criteria must be formalized as to the extent to which the HLW in the tanks must be separated for the residual waste to meet requirements for incidental waste (LAW) as well as the DOE definition of LLW and State of Washington definition of hazardous waste. Design specifications for HLW and LAW treatment will require that waste forms meet applicable criteria for disposal in the potential geologic repository, or as LAW for onsite disposal.

LAW disposal in onsite near-surface vaults was incorporated into the Ex Situ Intermediate Separations alternative, as well as all other ex situ alternatives except Ex Situ No Separations, because that is the current planning basis for the TWRS program as represented in the Tri-Party Agreement. The planning basis assumes that LAW will be vitrified and disposed of onsite in near-surface vaults. Further, it assumes that LAW will meet NRC criteria for incidental waste based on the extent of separations of LAW from HLW during the pretreatment process.

The disposal criteria for incidental waste is determined by the NRC and is well-established criteria. For the TWRS program, the issue at hand is whether the LAW waste stream, when vitrified, will be classified as incidental waste on the waste specifications. In the requests for proposals for Phase 1 of the privatization initiative, DOE defined the waste specifications for LAW that contractors would be required to meet. The waste specification was prepared to produce a waste that would be classified as incidental waste. DOE will consult with NRC to ensure that the waste meets applicable standards for incidental waste.

DOE and Ecology acknowledge the concerns regarding burial of vitrified cullet expressed in the comment. Cullet has a high surface area-to-volume ratio which results in lower long-term performance, including susceptibility to leaching. However, assuming vitrified LAW in cullet form for all of the ex situ alternatives provides a conservative analysis of the long-term impacts resulting from onsite retrievable disposal of LAW in near-surface vaults. Risks associated with retrievable disposal of LAW in vaults have been analyzed and these are presented in Appendix D.5. In addition, a Native American Scenario has been added to the Final EIS in Volume One, Section 5.11 and Appendix D. DOE and Ecology acknowledge the recommendation regarding consultation with Tribal Nations in determining LAW disposal criteria. Please refer to the response to Comment numbers 0035.04, 0012.11, and 0052.11 for related information.

Comment Number 0072.186

CTUIR

Comment P B-66: Sect. B.3.5: LLW is not the same as LAW, yet it appears that these terms are being used interchangeably. Because of this short time period for the review of this particular EIS. Please check for additional similar situations and correct them as is appropriate.

Response LLW is not the same as LAW. LAW is the waste remaining after removing as much radioactivity as practicable from HLW. The definition of LAW is provided in Volume One, Section 1.0, and addressed in more detail in Section 6.2. The term LAW used in Volume Two, Appendix B on page B-66 describes the waste stream after removal of the HLW components. The term is used correctly so no change to the EIS is warranted. Please refer to the response to Comment numbers 0005.25, 0072.118, 0072.117, and 0072.100 for issues related to regulatory definitions of Hanford tank wastes.

Comment Number 0072.187

CTUIR

Comment P B-95: PP 2: How will the insoluble sludges be suspended in the solution of soluble waste? How much volume of additional chemicals must be added? Will this be done in tank or in a receiving tank?

Response Following retrieval, where the sludges will be mobilized and suspended, the insoluble sludge particles will remain in suspension in the aqueous solution as long as the sludge particles have sufficient velocity. This velocity can be produced by such mechanical devices as pumps and mixers. The additional volume of chemicals to be added and the location of the addition point will be determined during the testing phase for this alternative.

Comment Number 0072.188

CTUIR

Comment P B-95: PP3: Why is it assumed that Cs is the only soluble radionuclide to be removed?

Response The engineering data package used in developing this alternative (WHC 1995j) assumed that only well-documented technologies would be used in developing the Ex Situ Intermediate Separations alternative. Cesium recovery by ion exchange is at present the sole technology that is well-documented for the recovery of soluble radionuclides. This assumption was then carried forward into the EIS. Removal of additional soluble radionuclides was included in the Phased Implementation and Ex Situ Extensive Separations alternatives.

Comment Number 0072.189

CTUIR

Comment P B-107: Sect. B.3.6: Calcining tank waste will result in a form not acceptable at the permanent waste repository.

Response The calcined HLW form would not meet the standard waste form (i.e., borosilicate glass) specified in the current waste acceptance requirements for the potential geologic repository. NEPA requires that an EIS address the full range of reasonable alternatives, including alternatives that would not be in compliance with laws and regulations. Please refer to the response to Comment number 0072.80 for a discussion of the NEPA requirement to consider reasonable alternatives regardless of their ability to comply with regulations. Volume One, Sections 3.4 and 6.2 and Volume Two, Section B.3 address regulatory compliance issues related to each of the alternatives. Please refer to the response to Comment number 0012.20 for a discussion of glass types and regulatory licensing issues.

Comment Number 0089.09

Nez Perce Tribe ERWM

Comment Page 3-66, Paragraph 2

It states that, with ex situ vitrification, LAW will be melted and flow into a water bath to break the glass formed into cullets, later the cullets will be bonded in a matrix material before onsite disposal. The EIS does not indicate what matrix material will be used to hold the cullets together. It is a concern that the matrix may not be as resistant to degradation as the vitrified glass allowing breakdown and waste surface area to increase. Whatever the matrix material is it will than also become LAW along with the glassformers used to create the product. Why not leave the LAW as a full size molded product rather than increasing the surface area for chemical breakdown by forming cullets. Surely a suitable configuration can be found for the molded LAW, that will not require forming cullets.

Response DOE and Ecology acknowledge the preference expressed in the comment and will take this preference and other public comments into consideration when making a final decision on remediating the TWRS waste. Matrix material composition and final waste form would be evaluated during the detailed design phase that would follow selection of this specific remedy, if this selection occurs. Volume One, Section 3.4 addresses waste composition and the reasons for assuming a vitrified low-activity cullet form. Cullet would provide processing and material handling advantages for high-capacity processing facilities; however, cullet has a high surface area-to-volume ratio, which results in lower long-term performance. Please see the response to Comment numbers 0005.40 and 0072.89 for a discussion of how the cullet waste form provides a bounding impact analysis. The response to Comment numbers 0035.04, 0052.11, and 0012.11 contain discussions concerning waste form.

L.3.4.8 Ex Situ No Separations Alternative

Comment Number 0005.48

Swanson, John L.

Comment The second paragraph under "Vitrification Process" on page 3-74 appears to be garbled. On balance, it appears to be addressing LAW vitrification, but it specifically says HLW glass.

Response The second paragraph under Vitrification Process on the referenced page may appear to discuss LAW vitrification, but the section heading is Ex Situ No Separations alternative, meaning that all of the glass waste produced is HLW. The first paragraph under Vitrification Process states that the HLW facility capacity is provided by two melters operating in parallel. The paragraph identifies HLW glass because this paragraph discusses only the HLW process as the only applicable process for discussion under this alternative. The text has been revised to clarify the discussion regarding vitrification under the Ex Situ No Separations alternative in Volume One, Section 3.4.

Comment Number 0057.07

Garfield, John

Comment Other things like the calcination case mentioned two calciners at a processing rate of 200 tons per day. You may be able to accomplish a solidified moltent sodium process at those rates but drying the waste to a calcine form would require something on the order of 20 to 40 calciners. The physics are not there to do it at a 100 tons per calciner. That is a technical error that should also be fixed.

Response A more detailed description of the conceptual calciner is discussed in Volume Two, Section B.3. The discussion in Volume One, Section 3.4 is a summary level discussion. The calciner design is modeled after available laboratory data. Additional details including mass and energy balances for the calcining process are available for review in the TWRS EIS Administrative Record and in DOE Reading Rooms and Information Repositories. Because the information contained in the Draft EIS is correct, no change to the text was made.

Comment Number 0072.112

CTUIR

Comment P 3-73: Sect.3.4.7: PP 4: Because this is a retrieval EIS not a closure EIS, this paragraph should be removed, or the language strengthened to indicate that there are several closure options.

Response Cost estimates for the removal and treatment alternatives included several Site closure assumptions (e.g., the Hanford Barrier), which are discussed in Volume One, Section 3.4.1.4, Major Assumptions and Uncertainties to provide an equal basis of comparison among alternatives. The text is considered appropriate within the context of the section and therefore no revisions to the text are required. For an extensive discussion of all issues related to closure, please refer to the response to Comment numbers 0072.08, 0019.03, 0019.04, and 0101.06.

Comment Number 0072.113

CTUIR

Comment P 3-74: Calcination Process: This process results in an unacceptable waste form for the permanent repository and thus this section should be removed or edited to clearly state the consequences of producing an unstable waste form that will spread to the environment.

Response DOE and Ecology acknowledge the preference expressed in the comment and will take this preference and other public comments into consideration when making a final decision on remediating the TWRS waste. The information requested in the comment is in the EIS. The Summary, Section S.7.1, Volume One, Section 3.4.7.7, and Volume Two, Section B.3.6.4 discuss the fact that the calcined waste form would not meet the current waste acceptance criteria for the potential geologic repository. NEPA requires that an EIS address the full range of reasonable alternatives, including alternatives that would not be in compliance with laws and regulations. For a discussion of this requirement, see the response to Comment number 0072.80. Volume One, Section 6.2 and Volume Two, Appendix B.3 also address regulatory compliance issues related to each of the alternatives. The radiological impacts of transporting the calcined HLW are analyzed in Volume Four, Section E.7.4.1.1.

Comment Number 0072.114

CTUIR

Comment P 3-76: PP 2: This paragraph relates to a process that produces a product that is unacceptable for the permanent waste facility, this paragraph should be removed or edited to clearly state the consequences.

Response Please refer to the response to Comment number 0072.113.

Comment Number 0072.115

CTUIR

Comment P 3-76: PP 3: S 2: This sentence refers to the closure process which is not within the scope of this EIS and should be removed or edited to clearly state the reasoning and the consequences and additional closure alternatives associated with this action.

Response Please refer to the response to Comment numbers 0072.112 and 0072.08.

Comment Number 0072.116

CTUIR

Comment P 3-77: Sect. 3.4.7.5: This section refers to the closure process and should either be removed or edited to reflect additional closure options such as the clean closure option of removing the tanks and the contaminated underlying soils as not to preclude all closure options.

Response Please refer to the response to Comment numbers 0072.112 and 0072.08.

L.3.4.9 Ex Situ Extensive Separations Alternative

Comment Number 0005.49

Swanson, John L.

Comment The first paragraph on page 3-80 refers to "--multiple complex chemical separations--." It appears to me that the use of the word "complex" is editorializing, and that word should be deleted. The last sentence of that paragraph says "--fewer radioactive contaminants--"; a more accurate statement would be "--lower concentrations of radioactive contaminants--"

Response It is true that the term "fewer radioactive contaminants" would mean less radioactive isotopes in the LAW and "lower concentrations of the radioactive contaminants in the LAW." The text in Volume One, Section 3.4 has been revised to reflect lower concentrations of radioactive contaminants in the LAW.

The term "complex" is intended to give the reader a feeling for the number, complexity, and level of development for the multiple separations processes used for the Ex Situ Extensive Separations alternative; therefore, the term conveys accurate and useful information.

Comment Number 0005.50

Swanson, John L.

Comment The second paragraph on page 3-80 includes Jacobs Engineering as a Site M&O contractor, which is incorrect.

Response The cited statement references information obtained from the Site Management and Operations contractor documents, one of which was prepared by Jacobs Engineering Group Inc. (i.e., Jacobs 1996), and does not state, nor is meant to imply, that Jacobs is the Site Management and Operations contractor. Therefore, the statement has not been revised.

Comment Number 0036.13

HEAL

Comment The EIS is inaccurate in addressing technical risk.

As noted above, DOE has conducted many analyses of the alternatives for treating and disposing Hanford tank wastes. Compared with many of these analyses, the EIS is relatively useless in communicating varying degrees of technical risk.

For example, following is a quote from the EIS on the technical risk involved with the intermediate separations technology: "Performance of key processes (e.g., solid liquid separation) has been assumed in the absence of substantive data" (p. 3-72). Next is a quote addressing the technical risk involved with extensive separations: "The key implementability issue associated with this alternative is that the performance of key separations processes has been assumed in the absence of substantive data" (p. 3-85).

The two above quotes say exactly the same thing: There is no qualitative difference between the technical risk involved in intermediate separations and the technical risk involved in extensive separations. Extensive separations is a complex, essentially science fiction technology that has little chance of becoming practical for use on tank waste. It has not been utilized except on a laboratory scale. Intermediate separations, on the other hand, has been used in several places and is relatively simple. The key concern is whether intermediate separations will work on the scale that it must to be useful to the tank program. The list of concerns with extensive separations is almost as long as the TWRS EIS. The approach in the EIS is tantamount to saying that building a car that can go 250 miles per hour involves the same amount of technical risk as building one that can go 2,500 miles per hour.

The position of the Northwest's stakeholders on this issue is clear: The TWRS Task Force stated:

The high cost and uncertainty of high-tech pretreatment and R&D threatens funding for higher performance low-level waste form, vitrification, and cleanup. Use the most practicable, timely, available technology, while leaving room for future innovation. Keep a folio of technological options and make strategic investments over time to support a limited number of promising options. Give up further research on unlikely options.

The lack of honest, frank text concerning technical risk seriously misleads the public and decision makers and unfairly prejudices judgement on the separations issue.

Response In response to the issue of assessment of technical risk; the EIS discusses the ability to implement the alternatives to provide additional information to decision makers. The implementability of a remedial alternative is a function of its history of demonstrated performance and its ability to be constructed and operated. In the case of both the Ex Situ Intermediate Separations and Ex Situ Extensive Separations alternatives, there is no history of demonstrated performance on the Hanford tank wastes. Bench-scale testing is currently underway for the Ex Situ Intermediate Separations alternative. No testing is underway for the Ex Situ Extensive Separations alternative at the Hanford Site; however, a process that is similar to the Intermediate Separations alternative is being used on the tank wastes at the Savannah River Site. It would be premature to state that intermediate separations has been used in several places and is relatively simple, especially with the operation problems that have occurred at the Savannah River Site. To provide the engineering information required for the EIS, the engineering data packages for both alternatives (WHC 1995e and WHC 1995j) assumed the performance of key processes in the absence of substantive data, leading to the same essential statement in the EIS. The inclusion of both the Ex Situ Intermediate Separations and Ex Situ Extensive Separations alternatives is the result of providing a range of reasonable alternatives to the decision makers, and no change has been made to the EIS. DOE and Ecology believes that the uncertainties are expressed in an unbiased and accurate manner.

Regarding the issue of alternatives that should or should not be considered in the EIS, NEPA requires DOE and Ecology to examine a full range of alternatives in the EIS. This range of alternatives must include a No Action alternative, and may then include other reasonable alternatives to allow an analysis of a full range of alternatives. Among the four major categories of alternatives examined in the EIS was a category involving extensive retrieval of the wastes from the tanks. Following retrieval, the HLW is separated from the LAW. The degrees of separation of these two types of wastes may range from no separations, to intermediate separations, to extensive separations. For more information on how the EIS developed alternatives consistent with the recommendation of the Tank Waste Task Force, see the response to Comment numbers 0072.05 and 0038.05. Because the information contained in the Draft EIS is correct, no change to the text was made.

Comment Number 0055.09

Martin, Todd

Comment The EIS is somewhat inaccurate in addressing technical risk for pretreatment. If you look at the language addressing the intermediate separations essentially sludge washing which we have a pretty good idea of how to do and the extensive separations which I have often characterized as science-fiction technology, the language is almost identical. It basically says there is uncertainty here because these are first of the time processes. I agree with that but one is much more technically uncertain the extensive separations than the other and I think the EIS should reflect that.

Response Please refer to the response to Comment number 0036.13.

Comment Number 0072.117

CTUIR

Comment P 3-81: PP 2-5: the LAW form as described here, is not an acceptable form because it does not meet the regulatory criteria, and the process results in a waste form that is very susceptible to leaching of high activity components. This section also needs to be redone to assume a glass form as the final waste product.

Response The Ex Situ Extensive Separations alternative would meet the requirements for disposal of HLW and LLW. However, residuals left in tanks would not meet the water protection standards if additional closure is not performed. Closure is not included in the scope of this EIS; however, closure for the tanks and residuals would be addressed in a future closure plan. The EPA is considering a rule to further regulate LLW disposal facilities; and the final design of the onsite LAW disposal facility may be impacted by EPA rule 40 CFR 193. A discussion of the ability of each tank waste alternative to enable DOE to comply with Federal and State regulations is included in Volume One, Section 6.2. Specifics of the matrix material and waste form would be final design issues. Volume One, Section 3.4 addresses waste composition and the reasons for assuming a vitrified LAW cullet form.

Please refer to the response to Comment numbers 0005.40, 0072.89, and 0072.107 for discussions of the cullet waste form and how cullet provides a basis for a conservative analysis of long-term impacts. The information requested in the comment is a level of detail that DOE and Ecology believe is not necessary for meaningful discrimination among the alternatives.

Comment Number 0072.118

CTUIR

Comment P 3-83: Sect. 3.4.8.4: Operation: The LAW description needs to be edited, removing the last two bullets.

Response Specifics of the matrix material and waste form would be final design issues; however, for the purposes of analyzing the ex situ alternatives in this EIS, LAW was assumed to be produced in vitrified cullet form. The referenced text correctly describes the operations involved in producing this type of waste form. Volume One, Section 3.4 addresses waste composition and the reasons for assuming a vitrified LAW cullet form. Cullet would provide processing and material handling advantages for high-capacity processing facilities; however, cullet has a high surface area-to-volume ratio, which results in lower long-term performance. Assuming vitrified LAW in cullet form for all of the ex situ alternatives provides a conservative analysis of the long-term impacts resulting from onsite disposal of LAW. No change to Volume One, Section 3.4 is required.

For a discussion of regulatory requirements for onsite disposal of LAW please refer to the response to Comment number 0072.111.

Risks associated with retrievable disposal of LAW in vaults have been analyzed and these are presented in Volume Three, Appendix D.5. In addition, a Native American Scenario has been added to the Final EIS in Volume One, Section 5.11 and Appendix D.

Please refer to the response to Comment numbers 0005.40, 0012.11, 0072.11, 0035.04, 0052.01, 0072.89, 0072.107, and 0072.117 for related information. Because the information contained in the Draft EIS is correct, no change to the text was made.

Comment Number 0072.119

CTUIR

Comment P 3-84: Sect 3.4.8.5: Post Remediation: second and third paragraphs: these two paragraphs need to be removed because this EIS is a retrieval EIS and closure options are not within the scope. If closure options were within the scope of this EIS then the option would necessarily be clean closure and removal of the tanks, underlying soil contamination, ancillary equipment, and MUSTs as not to prejudice future options for closure.

Response Please refer to the response to Comment numbers 0072.08 and 0072.112.

Comment Number 0072.190

CTUIR

Comment P B-115: Sect. B.3.7: The definition of LAW indicates that there will be a HLW component. This is unacceptable in terms of long term risk.

Response Volume Two, Section B.3.7.1 describes the extent to which the treatment processes are used to separate HLW from the tanks waste. LAW is the waste remaining after removing as much of the radioactivity as practicable. The definition of LAW is provided in Volume One, Section 1.0, and tank waste classification (e.g., Class A, B, C) is addressed in more detail in Section 6.2. NRC Class A waste contains the least amount of radioactivity. Long-term risk has been analyzed for each of the alternatives and waste forms, and this is presented in Volume One, Section 5.11, and addressed in more detail in Volume Three, Appendix D.4.7. Because the information contained in the Draft EIS is correct, no change to the text was made.

For more information on LAW, LLW, and HLW definitions, please refer to the discussions contained in the response to Comment numbers 0072.100, 0072.111, 0072.117, and 0072.118.

Comment Number 0072.191

CTUIR

Comment P B-119: Fig. B.3.7.2: This figure, to be acceptable, should have LLW exchanged for LAW and interim on site storage exchanged for on site disposal.

Response Figure B.3.7.2 accurately depicts the process flow of the Ex Situ Extensive Separations alternative described in Volume Two, Appendix B, Section B.3.7. Because the information requested in the comment was included in the Draft EIS, no modification to the document is warranted.

L.3.4.10 Ex Situ/In Situ Combination 1 Alternative

Comment Number 0005.09

Swanson, John L.

Comment The two combined ex situ/in situ alternatives discussed in the EIS speak of remediating a large fraction of the risk while remediating only a small fraction of the tanks. Such statements imply a knowledge of tank-by-tank inventory data that is much better than that given in the EIS. What data (or assumptions) were used for these alternatives? What accuracy do they have? Without evaluation of these factors, it is not possible to evaluate whether these combined alternatives are worth considering. Thus I feel that the current presentation of these combined alternatives is very biased in their favor.

Response DOE and Ecology acknowledge the preference expressed in the comment and will take this preference and other public comments into consideration when making a final decision on remediating the TWRS waste. The TWRS EIS addresses many potential criteria that could be used to develop a selection process and acknowledges that additional waste characterization and analysis would be required to implement this alternative (Volume Two, Appendix B, page B-127). Please also refer to the response to Comment number 0072.192. The data used for tank-by-tank analysis were based on SST and DST inventory data presented in summary form in Volume Two, Appendix A. DOE and Ecology believe that the existing historical data, laboratory data, and characterization reports, which provide the basis for the tank waste inventory used in the EIS, are adequate for detailed evaluation of impacts. The EIS acknowledges the uncertainties associated with the tank waste inventory, and accordingly uses a bounding approach to impacts assessment based on the available data.

The ex situ/in situ alternatives were developed to assess the impacts of combining two or more of the tank waste alternatives. Recognizing that tank waste differs greatly in the physical, chemical, and radiological characteristics, it may be appropriate to implement different alternatives for different tanks. These alternatives were developed to bound the impacts that could result from a combination of alternatives and are intended to represent a variety of potential alternative combinations that could be developed to remediate the tank waste. Because the information requested in the comment was included in the Draft EIS, no modification to the document is warranted. Please refer to the response to Comment number 0005.03 for a discussion of assumptions and uncertainty ranges used in the alternatives analyses.

Comment Number 0072.120

CTUIR

Comment P 3-86: Ex Situ/In Situ Combination Alternative: Technical staff agree that it may be necessary to implement an alternative treatment process for Tank wastes due to their varied contents, but the alternative of in situ treatment is unacceptable. The people of the CTUIR have been made involuntarily responsible for the waste DOE produced on CTUIR ceded land, and do not and should not, have to bear the responsibility of the enormous excess risk from in situ process. Therefore this alternative is unacceptable both in idea and in implementation.

Response DOE and Ecology acknowledge the preference expressed in the comment and will take this preference and other public comments into consideration when making a final decision on remediating the TWRS waste.

NEPA requires DOE and Ecology to examine a full range of alternatives in the EIS. The Ex Situ/In Situ Combination alternative was developed to assess the impacts that would result if a combination of two or more of the tank waste alternatives were selected for implementation. Because the tank waste differs greatly in its characteristics, it may be appropriate to implement different alternatives for different tanks. The Ex Situ/In Situ Combination alternative represents a combination of the In Situ Fill and Cap and Ex Situ Intermediate Separations alternatives, and as such can be considered as one of the reasonable alternatives for evaluation. It is intended to represent a variety of potential alternative combinations that could be developed to remediate tank waste. Because this alternative is one of the full range of alternatives developed in the EIS, the document has not been changed. For the Final EIS, a second combination alternative that was presented in the Draft EIS, has been fully described and impacts have been analyzed. This alternative is described in Volume One, Section 3.4 and impacts of the alternative are described in Volume One, Section 5.0 and associated appendices.

Comment Number 0072.192

CTUIR

Comment P B-126: Sect. B.3.8: This alternative is unacceptable in that there is an illegal in situ component. Additionally the characterization process has not adequately justified that they know where 90 percent of the contaminants that contribute to long term risk are located, or how to get at them for treatment.

Response DOE and Ecology acknowledge the preference expressed in the comment and will take this preference and other public comments into consideration when making a final decision on remediating the TWRS waste.

The Ex Situ/In Situ Combination alternative was developed to represent a variety of potential alternative combinations that could be developed to remediate the tank waste. Existing uncertainty associated with the tank waste inventory data must be resolved and additional tank characterization is required before final design of any alternative. Please refer to the response to Comment number 0005.09. Several activities that involve collecting and analyzing data on tank contents are ongoing, including the Tank Characterization program. Data obtained from this program would be used for refining remediation process design. Please refer to the response to Comment numbers 0012.14 and 0072.07 for discussions on characterization of tank inventory. Volume Two, Appendix A,

Section A.3 and Volume Two, Appendix B, Section B.1 address tank inventory data and ongoing waste characterization programs, and Volume Three, Appendices D and Volume Four, Appendix E address anticipated risk and accidents. Volume Five, Appendix K addresses the uncertainties associated with human health risks associated with this and other alternatives.

L.3.4.11 Phased Implementation Alternative

Comment Number 0005.51

Swanson, John L.

Comment Page 3-94 says "Separations prior to LAW processing--." I believe that the word IMMOBILIZATION or VITRIFICATION should be substituted for the word PROCESSING.

Response The Phased Implementation alternative description has been revised as follows, "Separations prior to LAW immobilization would be performed to remove the cesium, strontium, technetium, TRU elements, and entrained sludge particles from the waste stream to the extent required to meet LAW product specifications."

Comment Number 0005.52

Swanson, John L.

Comment The first two paragraphs on page 3-99 appear to be "lifted" from a privatization write-up, in that they talk of what functions are to be performed by DOE. This EIS assumes that all the functions will be performed by DOE.

Response Volume One, Section 3.4 has been revised as follows for the Phased Implementation alternative, "The waste (mainly DST liquid waste) would be retrieved and transferred to receiver tanks for LAW treatment." The cited text in Volume One has been revised as follows, "Separated cesium and technetium radionuclides would be stored at the treatment facilities or packaged for interim onsite storage at the Canister Storage Building."

Comment Number 0005.53

Swanson, John L.

Comment On page 3-99 it is stated that Phase 2 sludge washing will be performed in-tank. Is that really the intent?

Response The text regarding sludge washing has been revised in Volume One, Section 3.4 to remove the reference to in-tank sludge washing.

Comment Number 0005.54

Swanson, John L.

Comment I do not understand how the Phased Implementation approach can have R&D costs of only $190,000,000 (page 3-100) when those costs are $820,000,000 (page 3-71) for the intermediate separations alternative, which involves fewer pretreatment steps. Can you explain this?

Response Because Phase 1 of the Phased Implementation alternative would be a demonstration process, the research and development cost for the treatment process was assumed to be part of the Phase 1 cost. Research and development cost associated with the waste retrieval and transfer function was included at the same level as the other ex situ alternatives. Development programs currently are ongoing at the Site that are covered under the TWRS program or under other programs.

Comment Number 0032.05

Heacock, Harold

Comment In regard to the Department's currently planned method of implementing this program which is based upon the privatization of the work performance, we are not addressing that issue at this time. However, we have previously supported the privatization concept in other statements.

Response DOE and Ecology acknowledge the preference expressed in the comment and will take this preference and other public comments into consideration when making a final decision on remediating the TWRS waste. Comment numbers 0032.06, 0043.04, and 0060.01 contain information concerning privatization and associated issues related to privatization.

Comment Number 0032.06

Heacock, Harold

Comment Funding of the privatization program through the proposed budgeting set-aside at the expense of other Hanford Site cleanup programs and the concurrent failure to meet all Tri-Party Agreement commitments is not acceptable.

Response Changes to the TWRS program were incorporated into the Phased Implementation alternative, as required by the proposed 1996 Tri-Party Agreement amendments; therefore, Phased Implementation would not deviate from the Tri-Party Agreement or any other applicable regulation. DOE and Ecology intend to comply with all Federal, State, and local regulations and ordinances applicable to tank waste remediation. Funding for privatization is outside the scope of the TWRS EIS. The response to Comment number 0043.04 contains a discussion of privatization issues.

Comment Number 0035.06

Martin, Todd

Comment More specifically, I do not trust the costs just in general in the EIS. For example, the EIS assumes that for about 250 million dollars, the DOE can build a 20-ton a day low-level vitrification facility.

Everybody who has been in Hanford circles for years remembers that the Hanford waste vitrification plant, a one to three metric ton a day facility was going to cost one point three billion dollars.

What does the EIS say DOE can build essentially the same facility now for? About 232 million, about one-fifth the cost.

In totality, in the preferred alternative for phase one the EIS says that the two 20-ton a day vitrification facilities, two pretreatment facilities tied onto the side, and one HLW vitrification facility, in total five facilities, can be built for about one point four billion.

Again, I refer back to the one relatively small vitrification facility that DOE said that it would take one point three billion to build. I say no way can DOE build these facilities for that cost.

Are these costs due to privatization savings? The answer to that is no. The EIS does not deal with privatization. It assumes that these are traditional DOE facilities.

Further, if these costs are actually correct, there is not a need for privatization. The privatization set-aside account that everybody has been wrangling over the last couple of months has more than enough money in it right now to start building these facilities and get on with cleanup.

Either these numbers need to be changed, or we need to switch paths and start building vitrification facilities.

Response Please refer to the response to Comment numbers 0055,06 and 0057.06 for a discussion of the approach used to develop the cost estimate for this alternative.

The HWVP capital cost estimate is not directly comparable to the capital cost estimated for the Phase 1 HLW facility because it includes support facilities and infrastructure that are estimated as separate components for Phased Implementation.

The cost estimating methodology has been reviewed and revised cost estimates have been completed for the Phased Implementation and combination alternatives. These revised costs are shown in Volume One, Section 3.4 and in Volume Two, Appendix B.

Comment Number 0035.07

Martin, Todd

Comment Just in my cursory look at some of the other costs in the EIS things jump out at me. For instance, in the preferred alternative, phase one, basically DOE has to retrieve about 36 tanks to vitrify in that phase.

How much does the EIS say this will cost? Zero dollars. Not a penny. I think there are some retrieval costs there. There must be.

Response During Phase 1, readily retrievable and well-characterized DST waste would be retrieved and transferred to two DSTs used as receiver tanks for the demonstration facilities. This retrieval effort was assumed to be accomplished by using the existing tank farm work force and infrastructure, in the same manner that wastes currently are transferred. The cost associated with DST waste retrieval during Phase 1 was assumed to fall within continued operations. Continued operations costs of $1.58 billion, including 10,000 person-years of labor, were included in the cost estimate for Phased Implementation. The Draft EIS also states that selected SST wastes could be processed during Phase 1. It was assumed that wastes retrieved under retrieval demonstrations (e.g., tank 106-C) could be transferred to the demonstration facilities. Because the cost associated with these retrieval demonstrations is included in other programs, it is not included in the estimate for Phase 1, but is accounted for in the estimate for continued operations of the tank farms. The cost involved would be small in comparison to the overall project costs.

The Phased Implementation alternative identified in the TWRS Draft EIS would produce, during Phase 1, approximately 11 percent of the total LAW volume. Waste retrieval would not be required from 36 tanks during Phase 1.

DOE and Ecology have reviewed and revised the cost estimates for the Phased Implementation alternative for the Final EIS. These revisions are shown in Volume One, Section 3.4 and Volume Two, Appendix B, and are reflected in the

Summary.

Comment Number 0036.03

HEAL

Comment The costs in the EIS are incredible and must be redone. The EIS should not be finalized until a formal, credible data package for the preferred alternative is completed.

The EIS assumes the following for Phase 1 of the preferred alternative:

1. The cost of a 100 metric ton per day vitrification facility is half the cost of a 200 ton per day facility. There is no engineering data to support this assumption. In fact, there is data to refute it. About 15 percent of the cost of a vitrification facility is dependent upon its throughput (the rate at which it makes glass). Therefore, the cost of a 100 metric ton per day facility would be less than a 200 ton per day facility -- but not much less -- and certainly not 50 percent less.
2. The "six tenths rule" is an engineering rule used for extrapolating the cost differences between chemical facilities of different sizes. The EIS uses this to determine the costs of vitrification facilities of different sizes. This is a wholly inappropriate use of the rule. Again, it applies for facilities where about 85 percent of the facility cost is dependent upon processing equipment -- primarily chemical facilities. Vitrification facilities only have about 15 percent of their cost dependent on processing equipment. Therefore, vitrification facility costs are not particularly sensitive to sizing differences -- which means use of the "six tenths rule" results in grossly underestimated costs.

These two assumptions have resulted in grossly underestimated costs for the preferred alternative. The EIS estimates the cost of the Phase 1 facilities as follows:

- A 20 metric ton per day LAW vitrification facility can be built for $248 million.
- A 1 ton per day HLW vitrification facility can be built for $232 million.

Comparing these numbers to much more rigorously developed cost estimates we can see exactly how far off the EIS's numbers are. The Hanford Waste Vitrification Plant, which was designed to produce between 1 and 3 tons per day of glass, was estimated to cost $1.3 billion. This is almost exactly the same facility that the EIS says DOE can build for $232 million.

The EIS claims that for Phase 1 the total capital cost will be $1.4 billion. In other words, DOE is going to build two 20 ton per day LAW vitrification facilities, a one ton a day HLW vitrification facility and two pretreatment facilities for about the same cost as the one ton per day Hanford Waste Vitrification Plant!

Response Please refer to the response to Comment numbers 0035.04, 0035.06, 0055.06, and 0057.06.

Comment Number 0036.04

HEAL

Comment If the costs in the EIS are indeed accurate, there is no need for privatization.

If DOE's cost estimates are accurate, there is no need to take the extra risks of privatization. All of DOE's cries that there is not enough money to build vitrification facilities are false. The money DOE is currently putting in a set aside fund for privatization is more than enough to build these vitrification facilities.

Response Phased Implementation approach reduces the technical risk associated with tank waste remediation over a full implementation alternative. Phased Implementation also provides a greater opportunity to reduce overall program costs by applying lessons learned and experience gained during Phase 1 to the design and construction of the full-scale Phase 2 treatment facilities. The cost estimates developed for the TWRS EIS were developed using common assumptions. The Phased Implementation alternative cost estimate assumed the same contracting strategy, government-owned and contractor operated, as the other alternatives. As discussed in Volume One, Section 3.3, the EIS does not address the contracting strategy that would be used to privatize tank waste remediation. Please refer to the response to Comment number 0043.04 for more information.

Comment Number 0036.05

HEAL

Comment A cursory review of the cost estimates identified many other problems. Following are just a few: The EIS assumes that tank farm operation costs will be the same for both the Phased Implementation and Ex Situ Intermediate Separations alternatives. This is a faulty assumption. The Intermediate Separations alternative would begin treating waste in 2004 at a relatively high rate, resulting in tanks being emptied. This would allow DOE to dramatically reduce its tank farm operation costs. The estimate for operations for Intermediate Separations is $8.6 billion.

The operations estimate for the Phased Implementation alternative is also $8.6 billion. It should be much higher. Phased Implementation will treat waste at a much slower rate than Intermediate Separations, requiring DOE to fund operations programs for a longer period of time and thus at a higher level.

Response A difference in the rate at which the cost declined for different rates of processing is expected. Many of the factors that would control the ongoing tank farm operations cost would be the monitoring and maintenance requirements and how these requirements were reduced for individual tanks and tank farms. The monitoring and maintenance requirements for a tank farm may not be appreciably lower until all of the tanks within that tank farm are empty. The tank retrieval sequencing and blending strategy, which have not been finalized, would identify when waste retrieval from individual tanks and tank farms would be complete.

Because of the conceptual level of development, it was assumed for the purposes of the TWRS EIS that continued tank farm operations cost for Phased Implementation would be the same as for the Ex Situ Intermediate Separations alternative. In fact, the difference between level funding and the annual reductions in operating cost associated with the Ex Situ Intermediate Separations alternative for the years 2004 through 2011 totals $141 million or approximately 1.6 percent of the total $8,600 million used in the TWRS EIS for continued tank farm operations.

DOE and Ecology have reviewed and revised the cost estimates appropriately for the Phased Implementation alternative. These revised cost estimates have been presented in the Final EIS in Volume One, Section 3.4 and Volume Two, Appendix B.

Comment Number 0036.06

HEAL

Comment To support the Tri-Party Agreement, DOE must retrieve waste from 36 tanks in Phase 1 of the Phased Implementation alternative. The EIS estimates that this will cost $0. Surely there is a cost associated with retrieving the high-level waste from 36 tanks.

HEAL finds the estimates in the EIS to be utterly devoid of credibility and insists that the EIS not be finalized until a credible, formal data package for the preferred alternative is completed.

Response Please refer to the response to Comment number 0035.07 which addresses a similarly worded comment.

Comment Number 0036.11

HEAL

Comment The EIS must require vitrification as technology for tank waste treatment.

For all alternatives, except the Phased Implementation alternative, the EIS assumes vitrification will be the immobilization technology. The EIS provides no rationale as to why this alternative does not also require vitrification. Given that it is the preferred alternative, this is even more disturbing.

Vitrification has been the technology that stakeholders have found acceptable. It balances the concerns for a safe waste form with a relatively available technology that allows DOE to "get on with it." Any changes to the assumed use of vitrification must be accompanied by a compelling argument outlining any emerging technologies that better respond to stakeholder values. HEAL has not seen such an argument, and strongly doubts that one could be made.

The TWRS privatization initiative, upon which the Phased Implementation alternative was designed, also fails to require vitrification as a technology. It appears that this EIS has been designed to "fit" the decision to not require glass as a waste form in the privatization Request for Proposals.

Response Please refer to the response to Comment number 0035.02 which addresses a similarly worded comment.

Comment Number 0036.15

HEAL

Comment EIS does not show any effects of privatization.

DOE has spent over a year in an unsuccessful attempt to sell its privatization plan to the public. Cost is one of the many concerns that the public has raised with DOE. DOE has consistently held that privatization would cost 30 percent less than a traditional approach. DOE has been unable to furnish the public with any information that supports the above assertion.

The EIS continues the information void concerning the benefits of privatization. The EIS refers to privatization in the description of the Phased Implementation alternative, "under Phased Implementation, either DOE or a private contractor would design, build, and operate ... (the facilities)" (p. 3-23). As was pointed out above, DOE has held that the differences between a traditional government-owned, contractor-operated approach, and the contractor-owned and operated privatization approach were "revolutionary." Yet the EIS fails to show the different impacts of this revolutionary approach. Worse, the EIS is not explicitly clear about which approach -- privatization or traditional GOCO -- is being analyzed.

The EIS does allude to how the cost estimates for Phased Implementation were reached. It was developed by, "... combining applicable components from other ex situ alternatives and applying rations as required to account for differences in facility sizes and capacities and the degree of separations in LLW and HLW" (p. 3-99). Engineering data in the TWRS program over the years has shown that facility capacity and size do not have a large impact on facility cost.

The cost savings that DOE claims are virtually guaranteed are not evident in the EIS. The Tri-Party Agreement case is estimated to be $30-41 billion and Phased Implementation $32-42 billion. Where are the savings?

Response The EIS addresses the potential environmental impacts associated with a Phased Implementation approach to tank waste remediation. It was assumed for cost estimating purposes that the Phased Implementation alternative would use the traditional government owned-contractor operated contracting strategy. This was done to allow the reader to make an equitable comparison among the alternatives. A potential exists to reduce the cost for tank waste remediation by allowing the market place to establish, through the competitive bidding process, the cost for waste treatment. Cost savings projections that might result from privatization are not included in the EIS in an effort to maintain the competitive bidding process.

The fact that privatization is not addressed in this EIS is discussed in Volume One, Section 3.3. DOE believes that privatization will result in an overall cost savings for the project but has not published an estimate of savings that may result. The 30 percent figure identified in the comment is reasonably consistent with the cost savings resulting from other activities the federal government has privatized. Privatization is not within the scope of the EIS. Please refer to the response to Comment numbers 0036.05, 0036.04, 0055.06, and 0057.06.

Comment Number 0037.05

Elredge, Maureen

Comment Mostly I am concerned with further cost estimates throughout the EIS. They seem to be questionable. And I am particularly concerned that the preferred alternative is widely perceived as a privatization alternative which is supposed to save money, and yet this is not made evident in the document.

I want to urge you to use extreme caution both in assuming that the preferred alternative will be cheaper, and even more so in assuming that a privatization scheme will be a success.

When the cleanup program was being pummeled in Congress and the media last year, privatization was held up as the Holy Grail, sort of along the lines of please give us another chance. We will bring in corporate America. They will fix everything. We will be fine. Please give us our money.

We do not need Holy Grails. We need progress. We need action on the ground now. If privatization efforts fail it will be a disaster not only for Hanford but for the entire cleanup program. Thank you.

Response Please refer to the response to Comment number 0036.15, which addresses a similarly worded comment.

Comment Number 0038.06

Reeves, Merilyn

Comment The Board is troubled by some aspects of the preferred alternative, and where the EIS has not considered the impacts of privatization as a contractor mechanism.

Response Please refer to the response to Comment numbers 0036.15, 0036.05, 0036.04, and 0057.06 for discussions related to this issue.

Comment Number 0038.07

Reeves, Merilyn

Comment The concerns the Board has voiced have to do with liability in privatization, budget, regulatory, logistics, and public participation issues.

The Board has been dubious of DOE's ability to privatize, and has been disappointed in DOE's lack of responsiveness to the Board's concern.

Response Because the issues identified in the comment are not within the scope of the EIS, no modification to the document is warranted. Please refer to the response to Comment numbers 0036.04, 0036.05, and 0036.15.

Comment Number 0038.08

Reeves, Merilyn

Comment In regard to the specific technical approach, the Board has not been adverse to Phased Implementation. DOE has not made a case for that, privatized or not.

Response The TWRS EIS does not address privatization. The Phased Implementation alternative is based on the same common assumptions as the other alternatives to ensure comparability of the environmental impacts. However, the Phased Implementation alternative does address the technical requirements of remediating tank waste with a phased approach and impacts associated with that approach. Please refer to the response to Comment numbers 0043.04 and

0035.15, for more information.

Comment Number 0038.09

Reeves, Merilyn

Comment Phased Implementation can save money over the course of the program. The Board does remain dubious that Phased Implementation will save money, and will likely be more expensive. Again, our main concern has been with DOE's particular program of privatization.

Response The costs estimates developed for the TWRS EIS were developed using the same basis for all alternatives. The Phased Implementation alternative represents the traditional government-owned contractor-operated contracting strategy as described in Volume One, Section 3.3. Please refer to the response to Comment number 0036.15 for more information.

Comment Number 0038.11

Reeves, Merilyn

Comment The Board is concerned by the preferred alternative's effect on the Tri-Party Agreement. The Board has been and remains a staunch supporter of the Tri-Party Agreement.

The Phased Implementation approach has resulted in an unfavorable impact to the Tri-Party Agreement. The Tank Waste Task Force stated the following about the Tri-Party Agreement, quote, Tri-Party Agreement is in need of strengthening and improvement.

The Tri-Party Agreement should increase meaningful public and tribal involvement in all key Tri-Party Agreement decisions, with the public and the tribes as a partner in the goals, scope, pace, and oversight of the cleanup.

The process of the goal in the site specific advisory board and ongoing oversight of the agreement and improving pubic involvement is essential to achieving successful and satisfactory cleanup.

And our Board is trying to carry on these traditions. As we stated earlier, amendment four to the Tri-Party Agreement was judged to be very responsive to the above concerns.

Unfortunately concurrence in yet to be completed negotiations that will once again change the Tri-Party Agreement are somewhat or may be seen to be reversing the progress made in amendment four.

The Tri-Party Agreement changes that are being made in order to support the Phased Implementation alternatives are very disconcerting. The Tri-Party Agreement will go from a long list of interim and long-term enforceable milestones to only a handful of milestones, many of them not enforceable.

The changes will not increase meaningful public involvement or really involve site specific boards, the Hanford Advisory Board, in ongoing oversight of the TWRS program. And this is a step in the wrong direction.

Response The amendments referenced in the comment were based upon the privatization initiative. The Phased Implementation alternative merely bounds the technical approach of staged remediation of the tank waste and analyzes the potential impacts to support a comparison among alternatives. DOE and Ecology are cognizant of the Hanford Advisory Board's concerns regarding the remediation schedule and stakeholder and Tribal Nation participation in decision making. DOE is committed to meeting milestone commitments in the agreement and to effective and meaningful public and Tribal Nation involvement in the cleanup of the Hanford Site. Please refer to the response to Comment number 0012.19 (public involvement), 0072.149 (Tribal Nations consultation), and 0043.04 (privatization relationship to the Tri-Party Agreement).

Comment Number 0055.08

Martin, Todd

Comment Secondly, I think that the chart that Carolyn showed that had to do with the technical uncertainty of the various options was misleading on Phased Implementation. The rationale is that the technical uncertainty for this alternative is low because we are starting small and we are building. We will be able to employ learning. I think that is a very subjective call and I do not buy it. That option includes pretreatment processes have never been done before. Technetium removal. That is not low on the technical uncertainty scale.

Response The phased approach allows information to be collected and analyzed concerning retrieval, separations, and vitrification technologies before constructing full-scale plants. Lessons learned from the demonstration phase would be applied to the full-scale phase, which should improve the efficiency of operations of the second phase. This may reduce construction and operating costs during the second phase. The process of building demonstration plants to verify that technologies function effectively before building full-scale plants is a standard practice used in many industries where new technologies are being used. Because the information contained in the Draft EIS is correct, no change to the text was made.

Comment Number 0057.02

Garfield, John

Comment With respect to the summary slide, Todd made this same comment, the high-waste complex separations and treatment processes involved uncertainties that will be reduced by implementing the phased approach. I concur with the basic finding of the EIS in terms of the alternative chosen, however, instead of emphasizing the need to demonstrate technology, the emphasis should be on spreading early capital dollars and using a single facility to accomplish the mission. That should be the emphasis more than demonstration. There is no technical justification for demonstration philosophy with this process. The functions of sludge washing, cesium removal, and vitrification are not unknown technologies and any uncertainty with them can be demonstrated either radioactively hot at a laboratory scale or at large-scale cold with simulants much more efficiently than two low-level demos and one high-level demo. That will set the program back 5 to 10 years treated under 5 percent of the waste and cost something on the order of $3 billion dollars. That is a waste.

Response DOE and Ecology acknowledge the preference expressed in the comment and will take this preference and other public comments into consideration when making a final decision on remediating the TWRS waste. The demonstration process provides the opportunity to reduce overall program costs while completing remediation of the tank wastes within Tri-Party Agreement requirements, especially considering the uncertainty associated with the tank waste inventory. The lessons learned and process knowledge gained during Phase 1 would be incorporated into the design and operation of the full-scale treatment facilities during Phase 2. Please refer to the response to Comment number 0055.08.

Comment Number 0068.02

Martin, Todd

Comment Further, another one that is very easy for anybody to understand is you look at the EIS, and you see in Phase 1 they need to retrieve and vitrify the waste from about 36 tanks. How much would that cost? How much would it cost to pump the nuclear waste out of this auditorium if it were full? According to the EIS, zero dollars. Won't cost a penny. Surely there's a cost there. But the EIS doesn't reflect it. Again, the costs need to be fixed.

Response Please refer to the response to Comment number 0035.07 which addresses a similarly worded comment.

Comment Number 0072.121

CTUIR

Comment P 3-92: Sect. 3.4.10: This alternative is unacceptable if the implementation consists of decommissioning any process that produces waste acceptable to the HLW permanent repository, the added push of continuing to operate the test facility will reduce the time it take to finish the job.

Response DOE and Ecology acknowledge the preference expressed in the comment and will take this preference and other public comments into consideration when making a final decision on remediating the TWRS waste. Decommissioning of facilities for this alternative is addressed in Volume One, Section 3.4.

Comment Number 0072.122

CTUIR

Comment P 3-92: Phase 1: The selection of the SST waste is an integral component and effort has to be taken that this section include language reflecting that waste from all SSTs be test reacted as to ensure complete acceptability.

Response The waste processed during Phase 1 could include selected SST waste. As explained in Volume One, Section 3.4, the retrieval and treatment of the remaining DST and SST waste will be completed in the following stages of the alternative (Phase 2) following completion of the demonstration phase (Phase 1). Before any waste is retrieved it would be characterized and analyzed to ensure compatibility. Because the information requested in the comment was included in the Draft EIS, no modification to the document is warranted.

Comment Number 0072.193

CTUIR

Comment P B-132: Sect. B.3.9: This alternative, while good for a conservative industry approach does not take into account the uncertainties associated with the characterization program. Unless the demonstration phase proved beyond a doubt it could handle waste forms from all the tanks.

Response Considerable uncertainty associated with the tank waste inventory data remains, and additional tank characterization is required before final design of any alternative. Please refer to the response to Comment numbers 0012.14, and 0072.07 for discussions of characterization of tank inventory and characterization in programs. Phase 1 of the Phased Implementation alternative would include technical evaluation, demonstration, and detailed design for the separations and immobilization processes for various categories of waste feed. Following the successful implementation of Phase 1, Phase 2 would be implemented to complete the tank waste remediation according to the technical approach most appropriate to the tank waste categories. Because the information contained in the Draft EIS is correct, no change to the text was made.

Comment Number 0088.05

Porter, Lynn

Comment One of my concerns about the preferred alternative and privatization is who decides when it's a success or not. Is this strictly going to be the DOE deciding, or will the Tri-Parties together decide on this? And there need to be enough milestones in this, spaced closely enough together that the public interest groups can track this and know whether it's succeeding or failing, whether it's on track where it should be. Because otherwise this could go on for years, and all of a sudden, as it has before, all of a sudden we find out hey it's not working and we have to start over.

Response Privatization is a contracting mechanism that is not within the scope of the EIS. DOE and Ecology have agreed on a set of criteria that will be used in making a decision on whether privatization is achieving its intended goals or failing, which would cause a change from the primary path to the alternate path. Under this agreement, should Ecology determine that compliance with the primary path is unlikely, it will inform DOE of such an opinion. DOE will respond within 30 days whether a change from the primary to the alternate path is necessary. If DOE determines that a change is not necessary, it will provide Ecology with a written rational for continuing with the primary path. Ecology will have the authority at any time to require DOE to evaluate the viability of the primary path. These activities will be among the issues routinely statused, discussed, and reviewed by the Hanford Advisory Board and its Health Safety and

Waste Management Committee. Additional review, input, and comment by Tribal Nation regulator and stakeholder representatives is encouraged. Because the analysis requested in the comment is not within the scope of the EIS, no modification to the document is warranted.

L.3.4.12 Ex Situ/In Situ Combination 2 Alternative

Comment Number 0005.05

Swanson, John L.

Comment As an example of some of my concerns related to (3) and (4), I cite the "last minute" addition of the "Variation of the Ex Situ/In Situ Combination alternative." I do not see that this is a bounding case at all, and I see no evidence that it is based on anything more than some assumed characterization data (perhaps on computer predictions based on a set of assumptions). Thus, I feel that you got carried away by even proposing this as a separate variation; wouldn't it be better to discuss it in the context of being in the "noise level" of the very uncertain characterization data on which I am assuming the original ex situ/in situ alternative was based? (I am assuming this because you do not tell me the source of the "currently available characterization data" that you are basing this on, and I am not aware of any sound data bank that would allow this alternative to be factually based). (See Comment 0005.09).

Response The variation of the Ex Situ/In Situ Combination alternative (known as the Ex Situ/ In Situ Combination 2 alternative in the Final EIS) referenced in the comment was added to provide a range of alternatives that includes a combination of the in situ and ex situ alternatives. Without this alternative, there would have been only one alternative to represent partial retrieval, and it is important to show the public and the decision makers the relationship between environmental impacts and the extent of retrieval. This alternative provides one more alternative on the continuum from no retrieval to minimal retrieval to partial retrieval to extensive retrieval.

The variation of the Ex Situ/In Situ Combination alternative presented in the TWRS Draft EIS was based on limited data analysis and was therefore included in a brief preface to the Draft EIS, which provided general information on the levels of impacts that would occur as a result of implementing the alternative. This alternative has been developed and analyzed to the same extent as the other alternatives in this Final EIS. The variation is known as Ex Situ/In Situ Combination 2 alternative in the Final EIS. The information is presented in Summary, Sections S.5, S.6, and S.7; in Volume One, Section 3.4, and throughout Section 5.0. More detailed information on the alternative may be found in Volume Two, Appendix B.

Comment Number 0012.08

ODOE

Comment The EIS includes an attachment which describes a variation of the Ex Situ/In Situ Combination alternative. This alternative was not analyzed in the EIS and should be excluded from consideration for that reason.

Response The variation of the Ex Situ/In Situ Combination alternative analyzed in the Draft EIS was identified very late in the process of preparing the Draft EIS. DOE and Ecology choose to include a brief summary of this alternative as an attachment to the EIS. This alternative has been fully developed and incorporated into the Final EIS. DOE and Ecology believe the Ex Situ/In Situ Combination 2 alternative provides another alternative between the no retrieval and extensive retrieval, and, as a result provides useful information to the public and decision makers. Please refer to the response to Comment number 0005.05 for more information.

Comment Number 0047.04

Ahouse, Lorretta

Comment I am very concerned that an "attachment variation of the Ex Situ/In Situ Combination alternative" was added at the last moment to the Draft EIS. As I understand, this alternative would only remove 26 percent of the total tank waste volume and would not meet the Tri-Party Agreement. This is not acceptable to me as a citizen of

Washington State. Why was this alternative even added so late in the process if its does not meet the Tri-Party Agreement? Does the Department of Energy have any plans to seek an exemption from the Tri-Party Agreement? Why are we wasting taxpayers dollars to examine alternatives that are not legally acceptable? Please, just get on with the cleanup.

Response Please refer to the response to Comment numbers 0005.05 and 0012.08 which address similarity worded comments. Please refer to the response to Comment number 0072.80 for a discussion of the NEPA requirement to analyze reasonable alternatives, even when they do not comply with regulations. In the Final EIS the Summary, Section S.7 and Volume One, Section 6.2 address the ability of the alternative to comply with Federal and State regulations and the Tri-Party Agreement.

L.3.4.13 Miscellaneous

Comment Number 0005.11

Swanson, John L.

Comment I am quite sure that the alternatives involving in situ disposal will require more extensive/costly characterization activities than the other alternatives, but I do not see that reflected in the cost comparisons. Isn't that a bias in their favor? (I learned at the May 2 hearing that characterization is not included in this EIS, but my statement re biasing of comparisons stands. Also, shouldn't the omission of characterization from this EIS be highlighted, along with the omission of closure, so that it will be clear how limited in scope this EIS really is?)

Response Additional characterization requirements for in situ alternatives have been considered. Volume One, Section 3.4 acknowledges that additional characterization would be required for the in situ alternatives have been considered. The cost estimates completed in support of the Draft EIS included an additional $903 million for the in situ alternatives to cover additional characterization activities. These cost estimates are available for review in the TWRS EIS Administrative Record and DOE Reading Rooms and Information Repositories The relationship between closure and the alternative is presented in the Summary and Volume One, Section 3.3 and the impact in Section 5.0. For a discussion of the closure issues, please refer to response to Comment numbers 0072.08, 0101.06, and 0072.50.

Comment Number 0035.09

Martin, Todd

Comment Lastly, I would like to address the issue of mortgage reduction. This is something at Hanford that we have been dealing with for two years.

It has been a very high priority, and it has to do with putting money into old facilities for the purpose of closing them down in such a way that we could free that money up for real cleanup.

The tanks are the greatest mortgage reduction opportunity at Hanford we have. If we get the waste out of the tanks, we will reduce the budget by, as Dick said, about 300 million dollars. It is time to get on with it. It is time to do the job.

Response Cost associated with continued monitoring and maintenance activities at the tank farms would be reduced as the number of tanks containing waste was reduced. Remediation of Hanford tank waste is a needed investment to environmental well-being of the Hanford area and is required to protect human health and the environment.

L.3.5 CESIUM AND STRONTIUM CAPSULE ALTERNATIVES

L.3.5.1 Preferences for Capsule Alternatives

<u>L.3.5.1.1 Specific Preferences</u>

Comment Number 0006.01

Skyes, Megan

Comment As a scientist involved in biomedical research in the area of bone marrow transplantation, I am writing to express my support for the production of Cs-137 sources at the Hanford Reservation. It is my understanding that this is the only world producer of large Cs-137 sources other than the Russian laboratories at Mayak. In view of the high prices of Cs-137 sources that results from the existing monopoly, it will be nearly impossible to purchase sources in the future, as funding for biomedical research is becoming more and more limited. Therefore, the production of Cs-137 sources (at a lower cost) would be a major benefit to the biomedical research community. There are numerous other investigators, not only in the field of bone marrow transplantation, but in immunology who are dependent upon the availability of these irradiators in order to carry out their research. I hope that it will be possible for the Department of Energy to deal with the existing Cs-137 at Hanford in a cost-effective manner and in so doing to serve a vital need for the medical research community.

Response DOE and Ecology acknowledge the preference expressed in the comment and will take this preference and other public comments into consideration when making a final decision on the cesium and strontium capsules. For the Final EIS, DOE has identified the No Action alternative as the preferred alternative and has modified the Summary Volume One, Section 1.3 accordingly.

The TWRS EIS addresses alternatives for management and disposal of encapsulated cesium and strontium. The encapsulated cesium and strontium are included in the EIS primarily because they were originally extracted from the stored high-level tank waste to reduce the thermal heat generation in the tanks and would be considered HLW for purposes of disposal. DOE is actively seeking commercial interest in the beneficial applications for the encapsulated cesium and strontium, and DOE remains committed to pursuing any viable commercial or other beneficial uses; at this time, the preferred alternative is No Action. These uses would not be without substantial cost for reprocessing and repackaging since the current encapsulation was designed principally for storage purposes. If viable commercial or beneficial uses are not implemented, the capsules would be designated as waste at some point in the future and would be disposed of using methods consistent with one of the alternatives identified in the EIS or a new NEPA analysis would be completed. Under no action, the capsules will be stored and maintained under current operations at the WESF, which includes a comprehensive monitoring program. This program is described in Volume One, Section 3.2.

Comment Number 0008.03

Evett, Donald E.

Comment Secondly, S.5.2 Cesium and Strontium Capsule Alternatives: I personally would prefer to select alternative (4) physically mixing the capsule contents with the high-level tank waste, which would then be vitrified and disposed of at a potential geologic repository.

Response DOE and Ecology acknowledge the preference expressed in the comment and will take this preference and other public comments into consideration when making a final decision on the cesium waste and strontium capsules.

Comment Number 0029.02

Bartholomew, Dale C.

Comment I believe that cesium capsules should be left in a condition for possible future commercial irradiation. At the public hearing on May 2, 1996, we were advised that only one capsule leaked, but no one at the hearing was able to identify the mode of failure. If the mode of failure was a bad weld, I believe that it is premature to dispose of all capsules, because there still may still be some interest in commercial irradiation. It would be imprudent to waste all of the previous time, effort, and cost that went into the separation and concentration of the cesium-137 and strontium-90 isotopes.

Response DOE and Ecology acknowledge the preference expressed in the comment and will take this preference and other public comments into consideration when making a final decision on the cesium and strontium capsules. For the

Final EIS, DOE has identified the No Action alternative as the preferred alternative and has modified the Summary and Volume One, Section 1.3 accordingly. Please refer to the response to Comment number 0006.01.

Comment Number 0032.07

Heacock, Harold

Comment A secondary issue addressed in the Draft EIS is the disposal of the cesium and strontium capsules currently stored in the WESF facility at the B Plant.

We believe that any action to dispose of the capsules should be deferred at this time, so long as an adequate degree of environmental protection is maintained in their storage.

These capsules represent a resource that may have significant future use in irradiation programs. Pending the determination of their potential future utilization, we believe this potential asset should be retained.

This position is consistent with the Draft EIS since the high-level waste ex situ vitrification plant operation is at least 10 years away.

Ultimate disposal of these capsules with the other high-level waste is the preferred solution to the disposal of the capsules.

Response DOE and Ecology acknowledge the preference expressed in the comment and will take this preference and other public comments into consideration when making a final decision on the cesium and strontium capsules. Please refer to the response to Comment number 0006.01.

Comment Number 0040.05

Rogers, Gordon J.

Comment The cesium and strontium capsules should be transferred into air-cooled storage in the facility now being built for the Spent Nuclear Fuel project. In the meantime serious efforts should be made to see if there is a market for commercial use as radiation sources. Permanent disposal plans can wait.

Response DOE and Ecology acknowledge the preference expressed in the comment and will take this preference and other public comments into consideration when making a final decision on the cesium and strontium capsules. Please refer to the response to Comment number 0006.01.

Comment Number 0043.05

Hanford Communities

Comment The Hanford Communities would also like to comment on the plans for disposition of the cesium and strontium capsules currently stored in the B Plant. We believe that any action to dispose of the capsules should be deferred at this time. These capsules represent a resource that may have significant value. Rather than pay to dispose of these materials, the Department should actively explore opportunities for commercial use and sale.

Response DOE and Ecology acknowledge the preference expressed in the comment and will take this preference and other public comments into consideration when making a final decision on the cesium and strontium capsules. Please refer to the response to Comment number 0006.01.

L.3.5.1.2 General Preferences

Comment Number 0012.13

ODOE

Comment The second issue addressed by the EIS is what to do with the cesium and strontium capsules stored at Hanford. The cesium capsules contain cesium-135 and cesium-137. These two isotopes present different hazards. Cesium is very soluble in water. Cesium-135 has a long half-life. If it is disposed at Hanford, it presents an unacceptably large risk to public safety and health and the environment. Oregon supports disposal of the cesium and strontium from capsules in a suitable form to the national high-level nuclear waste repository. The waste form selected should ensure that cesium-135 will not endanger public health and safety or the environment.

Response DOE and Ecology acknowledge the preference expressed in the comment and will take this preference and other public comments into consideration when making a final decision on the cesium and strontium capsules. Please refer to the response to Comment number 0006.01.

Comment Number 0060.05

Davenport, Leslie C.

Comment I do not feel that a final choice can be made between the proposed alternatives yet. The No Action alternative of continued storage in WESF is acceptable during the next 10 years while DOE selects an alternate storage method for the capsules or determines if there is a use for them. I do not like the Onsite Disposal alternative because I feel that the capsules, if discarded, belong in the proposed geologic repository. Similarly, it makes little difference other than cost if the capsules are Overpacked and Shipped, or Vitrified with Tank Waste if a HLW vitrification facility is operational at Hanford.

Response DOE and Ecology acknowledge the preference expressed in the comment and will take this preference and other public comments into consideration when making a final decision on the cesium and strontium capsules. Please refer to the response to Comment number 0006.01.

Comment Number 0089.02

Nez Perce Tribe ERWM

Comment ERWM endorses the Overpack and Ship alternative for the strontium and cesium capsules.

Response DOE and Ecology acknowledge the preference expressed in the comment and will take this preference and other public comments into consideration when making a final decision on the cesium and strontium capsules. Please refer to the response to Comment number 0006.01.

L.3.5.2 No Action Alternative (Capsules)

No comments were submitted for this topic.

L.3.5.3 Onsite Disposal Alternative

No comments were submitted for this topic.

L.3.5.4 Overpack and Ship Alternative

No comments were submitted for this topic.

L.3.5.5 Vitrify with Tank Waste Alternative

No comments were submitted for this topic.

L.3.6 BORROW SITE SUMMARY

Comment Number 0019.03

WDFW

Comment WDFW is concerned by stating specific (potential) borrow sites in this document future decisions will be steered by the mentioning of such locations now. Statements are made in this document without the word "potential" even mentioned. Example, section B.6.1, paragraph discussing first and second layers, last sentence, which states "The proposed topsoil would be obtained from the McGee Ranch quarry site of the Hanford Site." This document appears to be trying to steer future decisions prior to exploring alternatives for borrow sites.

Throughout the document, the author states "future NEPA documentation will specifically address in detail impacts and mitigation of post-remediation tank closure where, for example most impacts of borrow site activities would occur" (page 5-258). The summary states "The impacts of closure cannot be meaningfully evaluated at this time. U.S. Department of Energy (USDOE) will conduct an appropriate NEPA review, such as an EIS, to support tank closure in the future." Since a meaningful analysis of impacts to potential borrow sites for post-remediation activities is not being undertaken by this EIS, WDFW requests all references to potential post-remediation borrow sites be deleted from the document (i.e., figures, tables, and text).

Response The TWRS EIS frequently states that the final selection for the borrow sites must be evaluated in the document for waste site and tank farm closure. The Summary states that, "The impacts of closure cannot be meaningfully evaluated at this time. DOE will conduct an appropriate NEPA review, such as an EIS, to support tank closure in the future." This question was also contained within the Notice of Intent to prepare the TWRS EIS.

Volume One, Section 3.6, states that, "The final selection of borrow sites for earthen material has not been made; however, the locations indicated represent potential borrow sites that would support each of the alternatives in both volume and location. Future borrow site decisions will be made in the ROD for the Hanford Remedial Action EIS."

Volume One, Section 4.5, states that, "The potential Vernita Quarry and McGee Ranch borrow sites have potential for both historic and prehistoric materials. Surveys have identified prehistoric or historic sites at both Vernita and McGee Ranch. The McGee Ranch area has been determined to be eligible for nomination to the National Register of Historic Places as the McGee Ranch/Cold Creek District. No prehistoric sites are known at the potential Pit 30 borrow site, although one structure from the homestead era is located at Pit 30." These statements are reiterated in Section 5.5 where it is stated that, "Archaeological surveys of the three potential borrow sites have identified a variety of prehistoric or historic artifacts and sites at the Vernita Quarry and McGee Ranch. The likelihood of disturbing additional archaeological sites in these areas is considered high." In addition, the archaeological importance of historic and prehistoric sites is reiterated in Volume One, Sections 5.5.1, 5.5.2, and 5.5.3.

Volume One, Section 5.17 identifies the potential Vernita Quarry and McGee Ranch borrow sites as undeveloped areas on the Hanford Site Development Plan's Future Land-Use Map. Further, using the potential Vernita Quarry site would involve expanding an existing quarry, while using the potential McGee Ranch borrow site would essentially be a newly developed site (though a small, old borrow area does exist). It is further stated that, "Planning for possible borrow sites for the TWRS program is still in its early stages and the CLUP and Hanford Remedial Action EIS address future land uses for the Site as a whole." Section 5.5.3 explains that any disturbance of the land surface, such as would occur in borrow site activity, is not compatible with the relationship between the Native Americans and the land.

Volume One, Section 5.20.1 states that, "Although much of the area proposed for the remedial activities is in areas currently disturbed, activities in some areas [primarily the Vernita and McGee Ranch borrow sites] have the potential to impact historic, prehistoric, or cultural sites. These areas have not been fully surveyed because they are potential borrow sites subject to change during final design. The final selection of borrow sites would be made through the Site Comprehensive Land Use Plan."

The discussion of alternatives uses these borrow sites as example locations for the materials that may be required for closure. Certainly, gravel and sand sources are required for construction of the facilities required for the various alternatives. In WHC-SD-WM-EV-103 and WHC-SD-WM-EV-104, Tables 6-12 and 9-12, respectively, state the assumption that an onsite gravel plant would provide crushed aggregate for concrete construction at a location 5 kilometers (km) (3 miles [mi]) from the construction site, the potential borrow site known as Pit 30.

Considering the earlier discussion, which states that the decisions for the borrow sites will be made elsewhere, that the prehistoric, historic, and cultural significance must be thoroughly evaluated, and the undeveloped status given to portions of the area land relationship with the Native Americans, DOE and Ecology do not believe that including these potential borrow sites alternatives for borrow sites. Using these named potential borrow sites provides only a basis to more completely discuss the potential impact of each of the alternatives covered in the TWRS Final EIS in terms of potential for traffic accidents with distance traveled, construction and operation emissions to the environment, a comparison between the alternatives, and an interrelated closure discussion for each of the various alternatives.

Comment Number 0019.07

WDFW

Comment Page 3-116, Tables 3.6.1, 3.6.2, and 3.6.3 If I were to open this EIS to this page, I would conclude from the titles of thee tables that a decision has been made on borrow site locations when in fact this document does not perform adequate NEPA analysis, i.e., a range of alternatives, for sources of different material types needed. WDFW requests all references to borrow site locations be deleted from the document since the impacts to borrow sites will require NEPA review.

Response Please refer to the response to Comment numbers 0019.03, 0072.08, and 0101.06. The EIS has been reviewed and revised as appropriate to clarify the assumed borrow sites as "potential" sites.

Comment Number 0072.123

CTUIR

Comment P 3-116: Tables 3.6.2. and 3.6.3.: These tables present figures that are for closure options. Because this EIS is a RETRIEVAL EIS, the tables are inappropriate and should be removed, or all of the closure options be equally presented.

Response The tables identified in the comment represent borrow materials required for the assumed closure scenario presented in the EIS. For more information on the closure assumption, please refer to the response to Comment numbers 0072.08 and 0019.03. As identified in the Draft EIS in Volume One, Section 3.3 closure is not within the scope of this EIS because there is insufficient information concerning the amount of contamination to be remediated. The amount and type of waste that remains in the tanks after remediation also may affect closure decisions. Closure as a landfill was included in all of the alternatives except the No Action and Long-Term Management alternatives so the alternatives could be meaningfully compared. This does not mean that closure as a landfill has been proposed or would be selected for final tank closure. Because the information contained in the Draft EIS is correct, no change to the text was made.

L.3.7 COMPARISON OF ACTIVITIES ASSOCIATED WITH ALTERNATIVES

Comment Number 0005.15

Swanson, John L.

Comment I find it strange that system costs is the only metric included in the summary description of each alternative in Section 3.0 ("Description and Comparison of Alternatives"). People are certainly interested in the costs, but the major concern on the part of the public appears to me to be in the perceived risk to their health and well-being. Couldn't/shouldn't summary data of some sort in that area be included in this section along with the cost data? If this is not done, I feel that you should change the title of this section to "Description and COST Comparison of Alternatives."

Response Volume One, Section 3.0 provides a description and comparison of the alternatives based on the characteristics of the alternatives themselves. These characteristics include cost. However, the section also provides a comparison of the processes inherent to each alternative; construction, operations, and post-remediation features of each alternative; the schedule, sequence of activities, and costs of each alternative; the amount of waste to be retrieved from the tanks, treated, and disposed of onsite verses offsite for each alternative. The potential environmental impacts associated with each of the alternatives are presented in Volume One, Section 5.0. In Volume One, Section 5.14, a summary table is provided that lists each alternative and all of the associated impacts as presented in Section 5.0. Additionally, a summary of those impacts was presented in the TWRS EIS Summary, Section S.7, which was prepared to accompany the EIS or to be read separately by individuals who did not want to read the entire EIS. The level of data and summarization of the data, as well as the presentation of the data and summary information provided the public and decision makers with the appropriate level of information in a format that was accessible considering the complexity of the proposed action and associated impacts. Because the information contained in the Draft EIS is correct, no change to the text was made.

Comment Number 0005.55

Swanson, John L.

Comment Why is the number of HLW shipments required for the Extensive Separations alternative ~50 percent as large as that for the Intermediate Separations alternative (page 5-146), when the ratio of the number of canisters is only ~10 percent as large?

Response The average rail trips per year calculated and reported in Volume One, Section 5.10, Trail Traffic Volumes, for the number of canisters generated as result of the Ex Situ Extensive Separations alternative has been modified in the Final EIS.

L.3.8 ALTERNATIVE CONSIDERED BUT DISMISSED

No comments were submitted for this topic.

L.3.9 MISCELLANEOUS

Comment Number 0005.59

Swanson, John L.

Comment Page vii of Volume Two contains incorrect definitions/descriptions of B Plant and T Plant.

Response According to two references, Hanford Tank Clean Up: A Guide to Understanding the Technical Issues (Gephart-Lundgren 1996), The Hanford Site: An Anthology of Early Histories (Gerber 1993), and T Plant (DOE 1994l), T Plant and B Plant were both constructed as plutonium removal facilities. Both facilities used the bismuth phosphate separation process. In later years, B Plant was used to remove cesium and strontium from acid waste pumped from the Plutonium-Uranium Extraction (PUREX) Plant. T Plant is currently used as a decontamination and repair facility. According to DOE 1994l, these plants, along with Z and U plants, for example, were given alphanumeric names due to 1940's wartime secrecy. These descriptions are provided in the Volume One Glossary. B Plant and T Plant were deleted from the Acronyms and Abbreviations list in Volume Two, Appendix B.

Comment Number 0005.60

Swanson, John L.

Comment On page B-9, an incorrect date is given for the start of the PUREX plant.

Response According to two references, Hanford Tank Clean up: A Guide to Understanding the Technical Issues (PNL 1996) and The Hanford Site: An Anthology of Early Histories (WHC 1992), the correct date for the PUREX Plant hot start up was January 1956. All applicable, incorrect references have been revised.

Comment Number 0022.04

Sims, Lynn

Comment There is no argument that Cold War Clean Up is extremely expensive. But inadequate clean up will be more expensive. Choosing less expensive options now will probably result in contaminated soils and water, serious loss of quality of life and health and perhaps loss of land use, trade, and commerce. Our costs now are a result of military production. Perhaps military clean up should be built in up front in the military budget since that is the department which seems to receive more funds than requested while DOE monitoring and clean up funds are slashed.

Finally, it must always be of paramount importance to remember that bomb production was implemented to protect this nation and that to skimp on efforts to clean up puts our homeland at serous risk forever.

Response Comment noted.

Comment Number 0025.01

Heart of America

Comment *A public interest group distributed a questionnaire at the Spokane and Seattle, Washington public meetings. Listed below are the questions and a tally of the totals from the 33 individuals who submitted surveys. The agency responses follow after the summary of the questionnaire. Below each question in bold is the ranking system contained in the questionnaire (using a scale of 1 to 10). In parenthesis following the rank are the number of individuals who circled the number on this questionnaire.*

Please tell us the degree to which you agree or disagree with the following proposals for Hanford's high-level nuclear wastes on a scale from one to ten with #1 being Strongly Disagree; #5 No Opinion; and #10 being Strongly Agree.

1. The current Tri-Party Agreement calls for retrieving 99 percent of the wastes from all of Hanford's high-level nuclear waste tanks by the year 2028 and turning it into some form of glass (vitrification). To what degree do you agree/disagree with the Tri-Party Agreement?

Rank: 1 (3) **2** (1) **3** (1) **4 5 6** (1) **7** (1) **8** (8) **9** (3) **10** (14) . **N/**A (2)

2. Leaving 75 percent of the high-level nuclear waste in the tanks forever, and filling them with cement or gravel after removing the most radioactive 25 percent would cost less than retrieving and vitrifying 99 percent of the waste. This is the Ex Situ/In Situ Combination alternative.

a. The cost savings claimed by USDOE for this option justify leaving most of the high-level nuclear waste in the tanks:

Rank: 1 (23) **2** (1) **3** (3) **4** (1) **5 6 7** (1) **8** (2) **9** (1) **10** (2)

b. USDOE has fully considered in the EIS the evidence that waste from tank leaks is moving towards groundwater and the risks this may pose to the Columbia River and future exposed populations from this alternative:

Rank: 1 (18) **2** (1) **3 4 5** (2) **6 7** (4) **8** (2) **9** (2) **10** (1) **N/**A (4)

c. Any alternative that leaves high-level nuclear waste in the tanks and in the soil beneath the tanks poses an unacceptable risk to the Columbia River and future generations.

Rank: 1 (1) **2 3** (1) **4 5 6 7 8** (2) **9** (3) **10** (27)

d. For the same reasons that the public voted in 1986 against Hanford being an underground high-level nuclear waste dump, leaving high-level nuclear waste in tanks or threatening groundwater is NOT acceptable:

Rank: 1 (2) **2 3** (1) **4 5 6 7 8** (4) **9** (2) **10** (25)

3. USDOE's Tank Waste Task Force (public interest groups, local governments, Tribes,...) urged USDOE to base decisions assuming that the wastes, after being vitrified, will stay at Hanford for a very long time, and not to assume USDOE will move the waste to its proposed Yucca Mountain repository. Do you agree/disagree with the advice:

Rank: 1 (6) **2** (1) **3** (2) **4 5** (5) **6 7 8** (1) **9** (7) **10** (11) **N**/A (1)

4. a. USDOE should use conservative assumptions that tank leaks move down to groundwater in less than 40 years, instead of claiming that leaks will stay close to the tanks and not reach groundwater for over 100 years:

Rank: 1 (1) **2** (1) **3** (1) **4** (1) **5** (1) **6** (1) **7 8** (3) **9** (2) **10** (23)

b. Because this EIS assumes tank leaks do not move quickly to groundwater, the EIS wrongly creates a bias in favor of delaying retrieval of all wastes from leaking single-shell tanks:

Rank: 1 (3) **2** (1) **3 4 5** (2) **6 7** (3) **8** (3) **9 10** (22)

5. a. Should the EIS drop (not include) the "repository fee" in its presentation of costs and as a basis for decision making?

Rank: Yes (22) **No** (12)

b. Does the inclusion of the repository costs appear to have biased the consideration of alternatives, including how one would weigh each alternative's risk versus costs?

Rank: Yes (26) **No** (4) **N**/A (3)

c. If the cost of the No Separations alternative (make all the waste into glass logs) were in the same price range as other alternatives when the hypothetical repository fee was not added onto it, would you urge that it be considered as a reasonable alternative to building multiple vitrification and separations plants:

Rank: Yes (19) **No** (10) **N**/A (5)

Comment Number 0027.03

Roecker, John H.

Comment Systems Engineering

In 1993 DOE proudly and loudly stated that it was going to use systems engineering to establish the requirements for both TWRS and also the Hanford Site. To my knowledge that has not been done in either case, yet here we are reviewing the EIS for implementing a very specific TWRS action. Looks to me as if the systems engineering commitment lasted about as long as the January 1994 Tri-Party Agreement. Two fundamental systems engineering actions are required to correct this situation. First, a top down requirements allocation from the site level to the program level is needed. Secondly, the TWRS Functions and Requirements Document, along with an integrated alternatives systems analysis, must be finalized and issued. I would request that issuance of the Final TWRS EIS be deferred until such systems engineering and analysis has been completed. Without such one cannot be sure that the right work is being performed or that the best alternative has been selected.

Response Since 1993, two systems engineering documents, TWRS Functions and Requirements (DOE/RL-92-60) and TWRS Systems Engineering Management Plan (DOE/RL-93-106) have been prepared. DOE conducted an independent Systems Requirements Review (SRR), submitted in November 1994, to validate the TWRS Functional Requirements Baseline. The SRR evaluated selected representative TWRS activities and identified the need for improvement in the implementation of systems engineering, quality of supporting documentation, and timeliness of testing assumed solutions and competitive alternatives. In response to the SRR, the TWRS System Requirements Review Action Plan (DOE/RL-95-74) was prepared, which addressed the findings presented in the SRR and presented the methodology for revising the Functional Requirements Baseline and developing the infrastructure required to support the functional requirements. Because the EIS and the TWRS Functions and Requirements have been developed concurrently, the conclusions of the TWRS Functional Requirements are anticipated to be consistent with the recommended alternative presented in the Final EIS. The information requested in the comment is a level of detail that DOE and Ecology believe is not necessary for meaningful discrimination among the alternatives. Please refer to the response to Comment number 0101.07 for further discussion of systems engineering.

Comment Number 0027.04

Roecker, John H.

Comment Technical Balance

I wish I was more interested in the projected cost of housing in the Tri-Cities in the year 2040 because there sure is plenty of computer printout data on that and other similar items, but I am just not. Instead, I would like to see more of the technical data that supports such items as operating efficiency, number of canisters, process design, alternative costs, etc. I would like to request that the reams of computer printout data and modeling contained in the appendices be restrained a little and more of the basic technical data that really establishes how an alternative is going to perform be put into the EIS.

Response The technical data that support the areas of interest indicated (i.e., operating efficiency, number of canisters, process design, and alternative costs) are contained in the TWRS Administrative Record and are available for review. The data to support the performance capability of the recommended alternative will be contained in the detailed design document for that alternative, which will be prepared following the Final EIS. The evaluation criteria used in the EIS are defined by NEPA and are confined to impacts to the environment only. As such, the requested evaluation of alternative performance data is beyond the scope of this EIS, but will be contained in future documents.

Comment Number 0027.06

Roecker, John H.

Comment Use of Non-Optimized Alternatives

The alternatives described in the EIS represent first cut approaches and do not represent optimized alternatives that have been tuned utilizing good engineering principles. More recent optimized process design flowsheet and facility design data is available and should be used in the Final EIS. This optimized design will significantly reduce the estimated cost.

Response The purpose of the EIS is to examine bounding alternatives, including a No Action alternative. It is anticipated that the optimized process design flowsheet will be used during the detailed design of the waste retrieval, transfer, treatment, and storage facilities conducted during the demonstration phase of the preferred alternative. The TWRS baseline flowsheet is continually updated and optimized. In order to support the EIS schedule, the baseline data used for development of the Draft EIS was frozen in May 1995. NEPA requires the alternatives be compared on an equitable basis. The Draft EIS presents conceptual alternatives that were developed using common bases that allow equitable comparison. Please refer to the response to Comment number 0072.05.

Comment Number 0027.08

Roecker, John H.

Comment Cost Estimates

In this day of tight budgets the cost estimate for an alternative is a very critical item. It is impossible to understand the basis for any of the cost estimates with the information contained within the EIS itself. It is necessary to look up several reference documents. This is not the easiest task if you do not live in the Tri-Cities. It would be helpful if the backup information for the life cycle cost estimates could be included in an appendix. There are several of the existing appendices that could be greatly reduced to make room for this information. As an example, the over 50 pages devoted to socioeconomic impact could be reduced to approximately 10 pages. The endless tables representing computer modeling printout could be put in a reference document.

Response As stated in Volume One, Section 1.0, the EIS fulfills the requirement for an analysis of potential environmental impacts in the decision-making process. NEPA and The Washington State Environmental Policy Act (SEPA) provide decision makers with an analysis of environmental impacts (both positive and negative) of proposed actions for consideration during decision making. This EIS presents the impacts of the proposed action and its reasonable alternatives for review and comment by the public and interested parties. Because of the magnitude of the cost required to implement any of the alternatives, it was determined that cost estimates would be included in the EIS. The development and presentation of alternative cost estimates is not the primary purpose or major focus of an EIS. The development of bounding alternatives for the EIS would indicate the need to develop additional cost data for the decision-making process.

The technical data used to develop the alternatives presented in the EIS are contained in the TWRS EIS Administrative Record and DOE Reading Rooms and Information Repositories. The Administrative Record contains additional cost estimate detail. As indicated in the front of Volume One, EIS technical reports, background data, materials incorporated by reference, and other related documents are available at Seattle, Spokane, and Richland, Washington; Portland, Oregon; and Washington, D.C.

The information requested in the comment is a level of detail that DOE and Ecology believe is not necessary for meaningful discrimination among the alternatives.

Comment Number 0027.09

Roecker, John H.

Comment My understanding of the capital cost estimates for the down sized facilities in the combination and Phased Implementation alternatives is that the sixth-tenths power rule was used. That is an absolute error. The sixth-tenth power rule does not work for these types of facilities. These facilities have a significant portion of their capital cost attributable to basic facility systems which are essentially independent of facility size. The sixth-tenth power rule works for facilities in which processing equipment makes up most of the capital cost. That is not the case with these waste processing facilities. That is something that must be fixed in the Final EIS. Conceptual cost estimates for the size facilities included in the EIS have been made. Why not use the available existing data which has backup rather than include erroneous data?

Response The cost estimating methodology has been reviewed for the Final EIS and revised cost estimates were completed for the Phased Implementation and combination alternatives. These revised costs are shown in Volume One, Section 3.4 and Volume Two, Appendix B. Please refer to the response to Comment numbers 0055.06, 0057.06, and 0035.06.

Comment Number 0030.01

Krieg, Ronald K.

Comment I am also disappointed in the limited scope that the inclusion of subsurface barrier technology in this Draft EIS was only as a potentially viable component to remediation alternatives, and am dissatisfied in Appendix B's level of analysis and conclusions of subsurface barrier technology. My other areas of concern involve the focus being on future impacts and conditions of alternatives alone with no regard to current or past practices. If the DOE is to develop a systematic approach to actually solving some problems in a truly cost effective manner with the least environmental impact, all aspects and pertinent details of all alternatives should be included in this EIS.

Response Subsurface barrier technology is discussed in Volume Two, Appendix B. Subsurface barriers are a potentially viable technology available to the decision makers. The EIS incorporates by reference (Treat et al. 1995) a detailed engineering feasibility study on subsurface barriers. Subsurface barriers were added as a potential mitigation measure in Volume One, Section 5.20 in the Final EIS. Please refer to the response to Comment number 0001.01.

All of the alternatives' future potential impacts are based upon an analysis of the potential impact of the alternatives themselves, without consideration of past or current practices, as appropriate. The information requested in the comment is a level of detail that DOE and Ecology believe is not necessary for meaningful discrimination among the alternatives.

Comment Number 0030.04

Krieg, Ronald K.

Comment The Hanford Federal Facility Agreement and Consent Order set a goal for the SSTs that no more than 1 percent of the tank inventory would remain as a residual following waste retrieval activities (3-31, Vol. 1). Many times it is stated that this retrieval criteria of 99 percent may not be achieved (3-101, Vol. 1). Residuals left in tanks would not meet the water protection requirements if additional closure action is not taken (6-30, Vol. 1), with these residuals having low solubility because substantial quantities of liquid was used in the attempt to dissolve or suspend wastes during retrieval (3-31, Vol. 1). Furthermore, performance of key alternative processes have been assumed in absence of substantive data. Cost estimates may have a high degree of uncertainty because some of the processes are unproven (3-100, Vol. 1).

The Tri-Party Agreement calls for total waste removal from Hanford's single- and double-shell tanks for processing and storage offsite, unless technically unfeasible. Throughout the EIS the word "uncertainties" is used regarding costs, COC inventories and volumes, technology performance, actual risks, and SST leakage quantities. It would be a shame to see uncertainty translate to unfeasibility. The time has come to eliminate uncertainty through a systematic, cost and risk effective remedial approach with the least long-term impacts to our future populace's health and environment.

Response As required by the CEQ, the TWRS Draft EIS identifies and analyzes the range of reasonable alternatives for the proposed action, which also includes a No Action alternative. All data that support the cost and impact analysis of each alternative are presented in an objective format for comparison by the decision makers and by the public during the comment period. However, the EIS is limited to the TWRS and evaluation of reasonable tank waste remedies. Under the Tri-Party Agreement, DOE and Ecology are bound to complete specific milestones related to tank waste remediation, and given the uncertainties listed in the comment, the Agencies have selected the Phased Implementation as the preferred alternative.

Identification and presentation of the many existing uncertainties was the method chosen by DOE and Ecology to complete the evaluations and publish the EIS. To consider and resolve all uncertainties before publication of the EIS would result in inordinate delay and failure to comply with the Tri-Party Agreement. Please refer to the response to Comment numbers 0005.03, 0072.05, and 0072.80 for discussions regarding regulatory requirements for bounding alternative analyses.

Comment Number 0030.05

Krieg, Ronald K.

Comment A recent report prepared by the National Research Council regarding containment-in-place technologies acknowledges subsurface barriers as an imperative use during remediation efforts and as a feasible interim solution to hazardous substance migration at Hanford and other Department of Energy sites. The committee's comparison of costs found retrieving and processing wastes costs $15 billion more (17.5 vs. $2.4 billion) than the alternative of in situ stabilization and isolation. I do not believe the Feasibility Study of Tank Leakage Mitigation Using Subsurface Barriers (WHC-SD-WM-ES-300) fully analyzed subsurface barrier technology and recommend what the National Research Council has; that containment-in-place technology be re-evaluated on its technical, fiscal, environmental, and public health merits as a possible short- or long-term alternative for radioactive waste management and inclusion as such in this EIS.

Another problematic issue is in Appendix B's level of analysis and conclusions of subsurface barrier technology, which failed to include information from the Feasibility Study of Tank Leakage Mitigation Using Subsurface Barriers regarding subsurface barriers' cost effectiveness when supporting clean closure activities. Although closure decision are not a part of this EIS, they are stated to be interrelated with the decisions made concerning remediation of tank wastes.

The conclusion I am referring to is stated: "The most cost effective individual action is adding a close-coupled subsurface barrier to support clean-closure. This result is lowering both risk and HI and the overall cost of the alternative. This apparent anomaly arises from the substantial reduction in contaminated soil and recovered contaminants requiring treatment when a subsurface barrier is used. The resulting cost savings more than offset the cost of installing the barrier (WHC-SD-WM-ES-300 Rev. 0, pg. 8-3). Information such as this must not be overlooked, forgotten, or excluded from this EIS.

A reduction in the financial risk involved with contaminant migration and the technical uncertainties of the ex situ technologies is possible and available now. The potential cost savings to TWRS could be in the $5-7 billion range if a 10-year delay in remediation costs could be attained through effective deployment of subsurface barrier technology. This principle would carry over to many other situations throughout the DOE complex. Mitigated through the use of effective subsurface barriers under the tanks a delay in start up could save money in two ways: 1) identical real budgets have lesser present value as they are postponed farther into the future, and 2) technology productivity improvements occur as time passes, further reducing real costs. This approach would allow the DOE to improve the design, construction, and operations of initial and full scale remedial operations to the SSTs.

Barriers for confinement-in-place of buried waste have been effectively used in many environmental remediation activities. Subsurface barriers provide a cost effective option for resolving the 200 Areas' management and remediation problems either as a short or long-term approach. With their continued development, cost efficient subsurface barrier technology providing the highest containment performance standards must be retained and given serious consideration on its technical fiscal, environmental, and public health merits for inclusion in this Draft EIS.

Response The subject report by the National Research Council, titled The Potential Role of Containment-in-Place an Integrated Approach to the Hanford Reservation Site Environmental Remediation, recommended that containment-in-place technology be considered and evaluated on its technical, fiscal, environmental, and public health merits as a possible short- or long-term alternative for radioactive waste management. Such analysis should be conducted on a site-specific basis.

For analysis in the EIS, alternatives that bound the full range of reasonable alternatives were developed. In order to bound the impacts associated with in situ disposal of the tank waste or tank leakage during waste retrieval activities, subsurface barriers were not assumed to be used. This does not preclude the use of subsurface barriers during remediation activities but provides an upper bound on the expected environmental impacts. Subsurface barriers would be beneficial for retrieval of wastes from known or suspected leaking tanks. This technology would be evaluated for tank-specific application. Subsurface barriers were added as a potential mitigation measure in Volume One, Section 5.20 in the Final EIS. Please refer to the response to Comment numbers 0001.01 and 0030.01.

Comment Number 0046.03

DiGirolamo, Linda Raye

Comment We ought to convert the WHOLE NUCLEAR INDUSTRY by forming a commission name NEW AGE ENERGY - touched upon by Mr. Browning - This NAE would begin research and development at Hanford while the DOE cleans up its awful mess...beginning immediately!

Response DOE and Ecology acknowledge the preference expressed in the comment and will take this preference and other public comments into consideration when making a final decision on remediating the TWRS waste.

Comment Number 0054.01

Belsey, Richard

Comment Grout did not work because we had so many processes going on. At Savannah River, they are today using grout because they were able with relatively simple separations to clean out 99.99 percent of the high activity fraction. But Hanford kept on, the Hanford's performance assessment kept on bouncing back over, over, strung out over time saying give us more information, your I-129 releases from the grout are still rising at 10,000 years. You at least have to model it out to know where it is going to turn the corner. I raise this question because we have re-opened all of those issues almost like re-opening a wound and looking at an infection again and saying why are we doing this and I would council that in fact you all list other stabilization forms (grout and ceramics) in this Draft EIS. How did we come to glass. There has been both a rich scientific literature about stabilizing radionuclides in glass going back 20 or 30 years and whereas with other substances there is spotty science and particularly with ceramics and grout there are highly variable reactivity. You go down to Savannah River it is almost like a witches brew. They stir it up and they have to use this particular kind of stone or else the whole thing does not gel and same thing with ceramic. So from my perspective, science wise we have to be careful about changing the stabilized waste form and we also now have about a 20-year, nearly a 20-year experience, not our own, but with other people using glass particularly for the high-level wastes. So I think that we should clearly not make any change in the waste form because of the inherent delay that will come about and the one thing we can not afford to do is to delay. The delays have cost nearly a billion dollars now and every year we delay costs that much more with by and large no real value so we got to get on with it. So state clearly that you are not going to consider anything except glass and glass from whoever gets to do the job of cleaning this up. I will leave that for now. Thank you very much.

Response DOE and Ecology acknowledge the preference expressed in the comment and will take this preference and other public comments into consideration when making a final decision on remediating the TWRS waste. NEPA requires that a full range of alternatives be examined in the EIS. This range of alternatives must include a No Action alternative, and may include other reasonable alternatives to allow analysis of a full range of alternatives. Some alternatives do not produce a glass waste form. Consequently, the EIS cannot omit glass from analysis as the waste form for a given alternative. It should be emphasized that for the ex situ alternatives, glass was the primary waste form to be produced. Similarly, the EIS also discusses alternate immobilization technologies to allow their analysis. These technologies were not included in the alternatives developed for impact analysis, but may serve as potential components of a remediation alternative. The discussion of alternate technologies, including grout, will be found in Volume Two, Section B.9.0. Because the information requested in the comment was included in the Draft EIS, no modification to the document is warranted. Please refer to the response to Comment numbers 0005.40, 0005.18, 0072.179, and 0009.08 for a discussion of issues related to grout.

Comment Number 0058.01

Swanson, John L.

Comment I have heard tonight different people give their biases. They blame somebody else for subjective judgement while they are drawing their own. In recent years have used a saying many times that I will repeat here. It applies to these costs analyses and comparisons of alternatives and that is the assumptions drive the conclusions.

Response When assumptions were made in the EIS, every effort was taken to ensure that these assumptions were applied equitably among the alternatives to ensure comparability. Please refer to the response to Comment number 0005.03.

Comment Number 0059.02

James Jordan Associates

Comment A brief white paper entitled, A Comparison of BNL's Small Modular HLW Treatment System with a Large Central Melter System is attached in support of JJA's request to include the BNL concept in the EIS analysis. Finally, an economic analysis of the estimated costs of producing high-level radioactive glass using the Small Module Inductively Loaded Energy concept invented by BNL is attached to this request. JJA has formally requested that the BNL concept be developed for possible use at Hanford and other DOE sites.

Response Alternatives were developed that bound the full range of reasonable alternatives and reflect the results of the public scoping process for the EIS and discussed in Volume One, Section 1.2. Representative alternatives that incorporate the range of cost, human and ecological health risk, and technologies have been developed for analysis in the EIS. The alternatives in the EIS have been developed to bound the applicable alternative technologies, including the one proposed by the commentor. Because the EIS contains bounding alternatives that will be presented to the decision makers, no change has been made to the EIS. Please refer to the response to Comment numbers 0072.05 and 0072.79.

Comment Number 0062.02

Longmeyer, Richard

Comment My second comment is with regard to the privatization. I have some concerns with regard to safety issues, as well as issues such as water quality issues. Both groundwater, and the Columbia River. The question is will the private contractors treat groundwater and the Columbia River with the same care that the government has been mandated to treat it, under the Tri-Party Agreement? Will they hold to the same safety guidelines, or perhaps better guidelines, that would be something that I would be interested to know.

Response Privatization is not within the scope of the EIS, as discussed in Volume One, Section 3.3 on page 3-13 of the Draft EIS, because it is a contracting mechanism. Under this concept, DOE would competitively bid a portion of the remediation work instead of having the Site Management and Operations contractor perform the work. Equivalent requirements for retrieval, treatment, and disposal of the waste, as well as quality and performance verification, would apply regardless of how DOE contracts to perform the remediation. Please refer to the response to Comment numbers 0009.19, 0060.02, and 0076.03.

Comment Number 0072.15

CTUIR

Comment It is difficult to follow the constituents through the various processes and into the environment. A mass balance showing distribution of the constituents for the tanks into various waste forms, effluents, and the environment would be helpful.

Response The detailed technical data developed to assess the environmental impacts of the alternatives addressed in the EIS are contained in referenced technical documents and calculations. The technical data are available for public review as a part of the TWRS EIS Administrative Record and in DOE Reading Rooms and Information Repositories. A mass balance for each of the waste treatment alternatives was completed in order to estimate the off-gas and liquid effluents. These off-gas and effluents streams then were used as sources in the risk assessment analysis. The human and ecological health effects from these off-gas and effluent streams are addressed in Volume One, Section 5.11. The TWRS EIS is a lengthy document and the inclusion of the detailed conceptual engineering information into the EIS would greatly lengthen the document. DOE and Ecology must balance the need to present relevant supporting data against the need to have a manageable and understandable document. The information requested in the comment is a level of detail that DOE and Ecology believe is not necessary for meaningful discrimination among the alternatives.

Comment Number 0072.196

CTUIR

Comment P B-166: Sect. B.7.1: It is noted that the evaluation for potential sites does not indicate that the affected Tribes were not notified or consulted with. If they were, please produce references, if they were not, please contact technical representatives of the affected Tribes.

Response The Draft EIS identifies in Volume Two, Section B.7 that the final site selection for the facilities associated with the ex situ alternatives has not been made. The potential site locations indicated in the EIS were taken from Hanford Site studies that examined potential site locations for the treatment facilities required for tank waste remediation and are included as examples for calculation of environmental impacts. The identification of these sites, within the 200 Area Waste Operations areas, is consistent with the Hanford Site Development Plan and the recommendations of the Hanford Tank Waste Task Force. As indicated in Volume One, Section 5.20, before to any ground disturbance activities, consultations would be conducted with the DOE Richland Operations Office Historic Preservation Officer, the Hanford Cultural Resource Laboratory, Washington State Historic Preservation Officer, and concerned Native American Tribal groups and governments. Consultation with Tribal Nations groups and governments would be performed early in the planning process to determine areas or topics of importance to these groups such as religious areas and potential resources of medicinal plants. Please refer to the response to Comment number 0072.149 for a discussion of the Tribal Nation consultation process for the TWRS EIS. Please refer to the response to Comment numbers 0019.03, 0072.235, 0072.50, and 0101.06 for related borrow site and closure information.

Comment Number 0072.236

CTUIR

Comment P E-202: Sect. E.10.2: Although not clearly stated, this appears to be the preferred alternative. Please confirm. Additionally, it appears that the only alternative for MUSTs involves filling them with grout (sand, gravel and cement). As we have stated on several prior occasions, the selection of an alternative that results in irretrievable waste forms may be unacceptable.

Response DOE and Ecology acknowledge the preference expressed in the comment and will take this preference and other public comments into consideration when making a final decision on remediating the TWRS waste. There has been no attempt in the accident analyses or at the location referenced in the comment to identify any alternative as the preferred alternative. The preferred alternative is identified in the Summary, Section S.7 and Volume One, Section 3.4.

For the ex situ alternatives, the MUST waste would be retrieved and only the residual left in the tanks would be grouted. Grouting of the MUST was included in the analysis to facilitate a balanced comparison of the alternatives. Closure of the MUSTS, like closure of the tank farms, will be the subject of future NEPA analysis. For each of the alternatives presented in Volume One, Section 3.4 and Volume Two, Appendix B, remedial actions for MUST waste are described. Because the information requested in the comment was included in the Draft EIS, no modification to the document is warranted.

Pollet, Gerald

Comment Hanford's Dangerous Nuclear Waste Tanks

They can explode! They do leak! Leaked waste will poison the Columbia River! So why does the U.S. Department of Energy want to consider leaving 75 percent of the waste in the tanks forever? Is this your idea of clean-up?

Response DOE and Ecology acknowledge the preference expressed in the comment and will take this preference and other public comments into consideration when making a final decision on remediating the TWRS waste. The EIS includes an analysis of potential accidents, including explosions, in Volume One, Section 5.12 and Volume Four, Appendix E. Past tank leaks are discussed in Volume One, Section 5.4.2. A discussion of the potential cumulative impacts of past tank leaks and the TWRS alternatives is provided in Volume One, Section 5.13 and Volume Four, Appendix F. The regulations (40 CFR 1500 to 1508) that implement NEPA requirements that an EIS address the full range of reasonable alternatives. For the TWRS EIS, the full range of reasonable alternatives was determined to range from leaving all of the waste in the tanks to retrieving as much of the waste as practicable (assumed to be 99 percent) and alternatives that fall between these two extremes. The DOE and Ecology preferred alternative is to retrieve 99 percent of the waste to the extent technically practicable. Please refer to the response to Comment numbers 0072.05 and 0009.01.

Comment Number 0085.03

Klein, Robin

Comment In the mean time we're calling for funding to develop real solutions. Not just for Hanford tank wastes, but to address soundly the global problem of disposing of dangerous radioactive materials worldwide. At the same time we're being asked to comment on TWRS. I'm going on a slight tangent here on purpose. We're also being asked to comment on the PEIS for disposition of weapons usable fissile materials nation wide. There we are faced with the ominous alternative, possibility of processing the worlds stores and reactors, with the likelihood that this could occur at Hanford. I hope that in parallel, with comments on what to do with the tank wastes, we don't lose sight of the pressure mounting to fire up reactors once again along the Columbia River. This is a non-solution to a problem, for which there is no good solution. Maybe if just a fraction of the dollars that were spent on developing those horrific weapons were spent on coming up with a permanent real solution, funding those great minds at the labs in Los Alamos Sandia, we'd probably stand a chance, and I believe we would. After all, that stuff's going to be around a while one way or another. But don't revive a failing nuclear industry at the price of health and safety of our futures.

Response DOE and Ecology acknowledge the preference expressed in the comment and will take this preference and other public comments into consideration when making a final decision on remediating the TWRS waste. Please refer to the response to Comment number 0040.01 for a discussion of factors influencing the evaluation of alternatives. Congressional funding issues are not included in the scope of this EIS. However, Volume One, Section 5.13 (Cumulative Impacts) addresses actions at other DOE sites and programmatic actions that could impact the Hanford Site, actions adjacent to the Hanford Site, and planned or reasonably foreseeable DOE actions at the Hanford Site.

Comment Page 5-15, Paragraph 2

The use of 1979 sitewide groundwater level measurements may not be a conservative approach to risk assessment as the groundwater mound at B pond forms a hydraulic barrier which delays and deflects tank wastes in the groundwater from traveling directly towards the Columbia River.

Response Please refer to the response to Comment numbers 0012.16 and 0072.259.

Comment Number 0091.01

Dyson, Jessica

Comment This new data showing contamination dangerously close to our groundwater would not even been told to us at this point if it was left up to the Department of Energy. This is vital information for the public to have and it does have significant impacts on the public. Almost all of our agriculture in Washington comes from eastern Washington and most of the land surrounding the Columbia River is irrigated with the rivers water. Any radiation in the groundwater will make it to the river and possibly to our dinner tables. It is your responsibility to account for all the risks to the public and be as conservative in your assumptions as possible to protect our communities.

Response DOE and Ecology are equally concerned about protecting the groundwater resources. The Draft EIS, in Volume One, Section 4.2 and Volume Five, Appendix I, documented that contaminants were present in the vadose zone beneath the tank farms and that one source of the contamination was past tank leaks. In Volume One, Section 3.3 the Draft EIS stated that new data were emerging that indicated contamination at lower levels than previously estimated. The new and emerging data are, in many cases, preliminary in that they indicate the presence of contamination beneath the tanks but do not provide any explanation on how they were transported. Potential contaminant transport mechanisms including chemically enhanced mobility of contaminants, preferential pathways (natural and man-made), and the effect of large liquid loss (as compared to the predicted losses for the TWRS remediation) were evaluated as part of the uncertainty analysis in Volume Five, Appendix K. This emerging information as well as future information that are being collected will be addressed by NEPA analysis for tank closure to ensure that the groundwater and Columbia River are adequately protected. The alternatives presented represent a full range of potential actions. The EIS incorporates "bounding" assumptions designed to result in conservative calculations of impacts. DOE and Ecology remain committed to selecting an alternative that will protect the valuable resources, which include the Columbia River, the groundwater beneath the tank farms and food sources produced in Eastern Washington. The preferred alternative would be protective of the groundwater and limit future contaminants from TWRS sources to well below drinking water standards in the Columbia River. An evaluation of potential Columbia River impact due to release of all tank waste is provided in Volume One, Section 5.2 and indicates that even for a large release, drinking water standards would not be exceeded. The preferred alternatives would release only about 1/100th of the waste and the rate of release would be slowed due to the infiltration-limiting cap over the tanks. Please refer to the response to Comment number 0030.02.

L.5.2.1 Groundwater

Comment Number 0005.19

Swanson, John L.

Comment I am troubled by "loose wordings" in many places; one example is in the area of the time required for leached contaminants to reach the groundwater. For example, the last sentence on S-27 says "The contaminants would reach the groundwater---", while the third sentence on 5176 says "Contaminated water would reach the groundwater---", the writers tend to use phrases like this interchangeably, but they do NOT have the same meaning because not all of the contaminants move through the soil at the same rate (deletion of the word "the" at the start of the first example would make them mean the same). This may sound like a picky matter, but I do not believe that is; for example, it is said that THE contaminants are x, y, and z and then it is later said that THE contaminants reach the groundwater after so many years, it can be concluded that x, y, and z all reach the groundwater at the same time. I believe that sentences should be accurate, so that readers do not draw incorrect conclusions because of poor sentences. This "time to groundwater" matter is addressed over and over again in the EIS, sometimes in sentences giving the correct meaning but more often not. I recommend that a technically correct sentence format be developed and consistently used for this issue (if it sounds repetitive, so be it-it is better to be accurate than to sound good).

Response Where applicable, the text of the EIS has been modified by replacing "the contaminants" or "contaminated water" with the phrase "the fastest moving contaminants."

Comment Number 0008.05

Evett, Donald E.

Comment S.6.2 Groundwater Pathways by Alternative: I consider the In Situ Vitrification as the best possible method. Your report signifies greater benefits, i.e.,:

1. The rate of leaching of contaminants would be very slow.
2. Contaminants reaching the groundwater would be small.
3. Greater the level of separations performed and the greater the effectiveness of the immobilization process.

Response DOE and Ecology acknowledge the preference expressed in the comment and will take this preference and other public comments into consideration when making a final decision on remediating the TWRS waste. The estimated long-term impacts of this alternative are lower than those estimated for other alternatives. These estimates are based in an assumption that the ISV technology can be developed to perform effectively. As discussed in Volume One, Section 3.4, there is much uncertainty concerning the development of this alternatives. This technology may be undergoing further testing to determine its effectiveness on large-scale applications. Modifications to this process have been suggested to improve potential effectiveness and to reduce the uncertainties on its application. Discussions related to ISV technologies are addressed in the response to Comment numbers 0023.01 to 0023.30 and in the response to comments located in Volume Six, Section L.3.4.6.

Comment Number 0012.15

ODOE

Comment Waste Properties

Report BHI-00061 on the T tank farm shows plutonium and americium deep under the tank farm. This was not predicted by USDOE's modeling. During operations, USDOE discharged large quantities of organic complexing agents to the tanks, including EDTA, HEDTA, tributyl phosphate and glycolic acid. These complexing agents have apparently bound-up a significant portion of the plutonium and americium and allowed it to move through the soil far faster than expected. The risk analysis should include these effects.

Response DOE and Ecology are aware of the contaminants under tank T-106 and the recently emerging information concerning contamination under other tank farms from past leaks. Past leaks and other closure issues are not within the scope of this EIS and will be addressed directly in future NEPA analyses for tank closure. See Volume One, Section 3.3.1 and the response to Comment numbers 0005.17 and 0072.08. Please refer to the response to Comment numbers 0040.06 and 0101.05 for a discussion of cumulative impacts. However, it is appropriate to provide in this EIS a qualitative discussion of past tank leaks and the potential transport mechanisms responsible for the contaminant migration.

Included in the uncertainty analysis provided in Volume Five, Appendix K are 1) descriptions of these data as they related to contaminant migration from past tank leaks; 2) a discussion of the various transport mechanisms that separately or in combination could have been responsible for the observed contaminant distribution beneath the tanks; and 3) how these mechanisms could impact each of the alternatives.

Report BHI-00061 contains borehole sample data collected as a part of a 1993 investigation of contaminant migration from a leak from tank 241-T-106. The data from the 1993 investigation consist of 43 split-spoon samples from borehole 299-W10-196. These samples were taken for physical, chemical, and radiochemical analysis in addition to spectral gamma geophysical logging of the borehole on eight occasions.

The 1993 investigation resulted in data on the vertical distribution of several radionuclides and chemicals. Most notably are the following results.

- Plutonium concentrations increase dramatically at the depth of the bottom of the tank (33 feet), reach a peak at 43 feet, decrease to less than 1 pCi/g at 92 feet, spike at 95 feet, and then decreases to background at greater depths.
- Cesium-137 had a significant concentration within the fill around the tanks to a depth of 13 feet, above the presumed depth of the tank leak. The concentration decreased until a depth of 30 feet, then began to increase to a maximum at 43 feet, followed by a decrease to below background until two spikes were detected at 78 and 101 feet.
- The spikes at approximately 100 feet are observed for both mobile (e.g. technetium-99) and attenuated (e.g. cesium-137) contaminants and are believed to be concentrated by a caliche layer that occurs at this depth. This may be due to a hydraulic conductivity contrast, adsorptive capacity from the increased clay content, and/or substitution of radionuclides in the calcium carbonate.

The findings from the 1993 investigation of the tank T-106 leak along with potential contaminant transport mechanisms are discussed in Volume Five, Appendix K. The data from this investigation are expected to be the basis for additional NEPA analyses for closure which will directly address potential mechanisms affecting the fate and transport of leaks from the waste tanks.

There are many possible contaminant transport mechanisms that may be responsible for the contaminants observed at depth. These mechanisms may include: chemically enhanced mobility of otherwise relatively immobile contaminants, large fluid loss from tank(s) or other sources to provide driving force, naturally occurring vertical features such as clastic dikes that may be more transmissive than the layered sediments, and inadequately sealed drywells. These potential transport mechanisms were discussed in Volume Five, Appendix K as part of the uncertainty analysis and so that mitigating measures could be developed. Each of these mechanisms is briefly discussed in the following paragraphs.

There are two general types of chemically enhanced contaminant mobility that are of concern to DOE and Ecology: 1) the chelation of some contaminants such as cobalt by complexing agents such as EDTA resulting in smaller K_d values and faster transport through the vadose zone; and 2) competition for cation exchange sites by elements such as sodium, which could result in a smaller K_d and faster movement through the vadose zone for contaminants such as cesium, whose transport is believed to be retarded largely by cation exchange.

The magnitude of fluid loss, while not a transport mechanism, can greatly affect the rate and distance a contaminant moves. The source terms (i.e., liquid loss per unit time and contaminant concentration) for the TWRS are quite different (smaller) than would be expected for many of the past tank leaks. This difference is in part, why the earliest predicted contaminant arrival at the groundwater for the TWRS alternatives is approximately 130 years (No Action alternative); whereas contaminants previously leaked from the tank may be arriving at the groundwater within a 50-year period.

Vertical zones of high transmissibility, whether from man-made features such as inadequately constructed drywells or natural features such a clastic dikes filled with clean sand, would result in faster contaminant transport. The drywells were constructed using a cable tool drill and the annular space between the casing and borehole was not sealed. Clastic dikes are geologic features that occur in the area. They are often vertical or near vertical and can also be found horizontally. The hydraulic nature of these features on the Site are not well known but they could be preferential pathways for contaminants to migrate vertically.

Comment Number 0012.16

ODOE

Comment Risk Models

The risk modeling in the EIS is sufficient to support the proposed action. We do not believe it is sufficient to support any decision which would leave waste in Hanford tanks.

The risk analysis included in the EIS uses simple linear models and simple waste source term parameters as surrogates for reality. The soil structure and hydrogeology are complex. Despite extensive drilling, boring and testing, no accurate or adequate model exists of the geohydrology of the Hanford Site. This is evident by comparison of the risk maps presented in this EIS with the draft Hanford Remedial Action EIS. These two EISs use data gathered several years apart to predict the flow paths and travel times for movement of radioactive materials through the soil and groundwater. A minor difference in input data results in large differences in movement of the wastes and larger differences in when and where the wastes are expected to reach the Columbia River.

The soil at Hanford has layers with widely varying properties. Some layers allow easy movement of water. Others slow water movement. Some layers show different horizontal and vertical rates of water movement. Simple linear models cannot adequately model the behavior of such complex systems.

We believe the modeling is also flawed by arbitrary changes in the values used for the physical properties of the soils. Page F-58 of Volume Four contains two example: 1) "Kincaid et al. (1993) specified a value of 0.498 for $_{s}$ in the Ringold Formation in the vicinity of the 200 East Area. This value was considered unrealistically high; therefore $_{s}$ and the related S_{wr} and $_{r}$ values were changed to the values reported for the Ringold Formation in the 200 West Area."; and 2) "The value reported for $_{r}$ in Wood et al. (Wood et al. 1995) was 0.0. It was assumed that the reported value was below detection and was reported as zero. Therefore, a small number (0.001) was assumed in its place to maintain the relationship between $_{s}$ and S_{wr} stated previously."

Page F-59 details other "simplifying assumptions." We have no assurance these simplifying assumptions are reasonable. They may or may not result in conservative evaluation of the risks. Combined with the other arbitrary changes and simplifications, the result may be great differences in the real risks compared to modeling results from the modeling.

Response Soil structure and hydrogeology of the Site are complex. Most important is the conceptual model of water movement through the vadose zone, into the underlying aquifer, and ultimately discharging to the Columbia River. The conceptual model for this EIS is based on observations that include geologic structure, the pattern of geologic materials deposited in the vadose zone and underlying aquifer, existing contaminant migration, and the bounding effects of features such as the Columbia River, the Yakima River, and Horse Heaven Hills. This results in an expectation that most of the contaminants from the tank sources will move in a west to east/southeast direction with a small amount flowing northerly through the gap between Gable Butte and Gable Mountain. These results are generally obtained using the 1979 water level data set, on which all of the groundwater assessments are subsequently based. The 1979 water level data represent a period of relatively steady conditions. Volume Four, Appendix F compares the EIS model results with results calculated assuming the decay of all 200 Area groundwater mounds, and the two sets of results parallel each other very closely.

The water level data set used by the HRA EIS is based on data from 1992. While this is more recent data, it is also for a period of large change with regard to wastewater disposed to the soil column. It also represents a period in time where, briefly, most contaminants from the 200 Areas flowed north through the gap between Gable Butte and Gable Mountain. Please refer to the response to Comment numbers 0030.02, 0091.01, 0069.07, and 0069.03 for additional discussions of issues related to risk.

Krieg, Ronald K.

Comment My first area of concern is the focus of being on current impacts and conditions alone. This EIS states: "Previously leaking contaminants are not in the scope of this EIS (5-48, Vol. 1)." Past contamination should be. Rust Geotech's recent tests have sampled cesium-137 as deep as the well sampled, 125 feet below the surface (Seattle PI). During the 1970's, as much as 1 million gallons of water was sprayed into single-shell tank 105-C in order to facilitate cooling. It is unlikely that 800,000 gallons of this contaminated cooling water has escaped into the surrounding soil and groundwater (WHC-EP-0182-34). Dissimilar estimates of total SST leakage from various studies range from 600,000 to 1,000,000 gallons. In the Hanford 200 Area 67 tanks are known or assumed to be leaking, and on average, one additional tank begins to leak each year. Approximately 30 tanks have not been interim stabilized with eight of the SSTs that are assumed leakers yet to be stabilized. Following interim stabilization, an SST can contain as much as 189,000 L (50,000 gal) of interstitial liquid (Vol.1, pg. 3-41). This process only minimizes potential releases, it does not provide relief to long-term impacts or relieve the possibility of continued leakage as this EIS awaits review and a Record of Decision is made.

Response Previously leaking contaminants from the tanks are not within the scope of this EIS. However, these contaminants are given some consideration in the EIS, and they will be addressed in future NEPA analysis. Please refer to the response to Comment numbers 0005.14 and 0072.08. The Draft EIS acknowledged the emerging information associated with contaminants beneath the tanks. The time between the Draft EIS and the Final EIS has afforded evaluation of some of these emerging data. These evaluations are presented in the Final EIS in Volume Four, Appendix F and Volume Five, Appendix K. Contaminants beneath the tanks are being considered in this EIS, though they are not considered as directly as in future NEPA analyses for closure. Past-practice leaks from the tanks are addressed as one component of the cumulative impacts presented in Volume One, Section 5.13. The Hanford Barrier would be used in the second phase of the preferred alternative. The Hanford Barrier will be designed so that its areal extent would mitigate the potential of infiltrating precipitation mobilizing contaminants below the tanks in the vadose zone (please refer to the response to Comment number 0089.08). It is important to understand the potential contaminant mechanisms in the vadose zone that could have resulted in contaminants moving near the groundwater table so that mitigating measures can be considered. A discussion of the potential transport mechanisms that associated with the occurrence of tank-related contaminants over 100 feet below some of the tanks is provided in Volume Five, Appendix K. The comment mentions hundreds of thousands of gallons of water leaking from some of the tanks, which is an important point. Such large volumes of water entering the vadose zone over a short period of time are dissimilar to the types of source terms associated with any of the TWRS alternatives, and may be one of the mechanisms which caused the contaminant migration in the vadose zone. See the responses to Comment numbers 0012.01, 0012.15, and 0091.01 for additional related information.

Comment Number 0030.03

Krieg, Ronald K.

Comment Retrieval operations cited in this EIS involve hydraulic or robotic sluicing. A conservative figure of 4,000 gallons of leakage per tank is assumed in this EIS. It is stated in the Feasibility study leaks could range to 40,000 gals in tank 241-C-106 for traditional sluicing. This same study averaged estimated leaks at approximately 10,000 gals for traditional sluicing with the average for robotic sluicing at 4,000 gals. Regardless of conflicting numbers or arguments of source credibility and test results, retrieval options being considered will add additional contamination through leakage, thus further compounding contaminant saturated soil and the threat to groundwater.

Response The amount of leakage resulting from tank waste retrieval will vary. Certain tanks are of recent construction and have had few problems while in use. These tanks can be expected to leak very little, if any, during retrieval. Other tanks were constructed decades ago and then received rather severe use. Rather than attempting to assess potential for leakage on a tank-by-tank basis, the EIS assumed that on average, each SST would leak 4,000 gallons during retrieval. The inventory from these leaks was assumed to be the average tank inventory, which is conservative since much of the leaks would likely be sluicing liquids with lower levels of contamination. This provides an upper bound on the potential impacts, a nominal case using the inventory of the slucing liquids for a portion of the release is included in the Final EIS. Retrieval losses would add contamination to the groundwater. In the alternatives where tank waste is retrieved, the losses during retrieval are part of the starting source term for the groundwater modeling. Volume Four, Section F.2.2.3.5 of the EIS discusses contaminant losses during retrieval. When additional data become available to assess retrieval losses on a tank-by-tank basis, these potential losses may be recalculated. Until such data are available, an average loss during retrieval must be estimated.

Comment Number 0036.14

HEAL (Exhibit)

Comment The in situ alternatives have a faulty assumption.

For the No Action, Long-Term Management, and In Situ Fill and Cap alternatives, the EIS assumes that no leaks will happen during the administrative control period. This is a dubious assumption. Given the state of the tanks, it is safe to assume that there will be escalating tank leaks during such an extended administrative control period.

Response Accurately predicting the number or severity of tank leaks that will occur in the future is difficult. One factor that will increase the number of leaking tanks is the age of the tanks. As the tanks get older, the probability of a leak increases. The number of leaking tanks may decrease as well as pumpable liquid is removed from SSTs under the interim stabilization and salt-well pumping program. Using administrative controls, such as free liquid removal from the pore space and other voids in the tank solids and the sealing of tank entrances to prevent fresh liquid from accidentally entering the tanks will minimize the number of potential leaks. Because future leaks cannot be accurately predicted, the assumption was made that all the tanks of a given type would leak at some predetermined time in the future. This assumption may not represent an accurate prediction of the future, and the impacts of the 100-year administrative control compared to the 10,000-year risk may not be substantially different, but this assumption allows an even-handed comparison of the long-term environmental impacts of the proposed alternatives. For further discussion of continued tank farm operations and tank waste storage, see Volume One, Sections 3.2.1.4 and 3.2.1.5, respectively. Please refer to the response to Comment number 0072.85 for a discussion of potential leaks during the 100-year administrative control period.

Comment Number 0040.06

Rogers, Gordon J.

Comment Monitoring of vadose zone below the HLW tanks and of the groundwater plumes should be continued to assess the rates at which contaminants reach the groundwater and the Columbia River. There will be ample time to detect any real threat to the users of river water; and to take action if a real threat is shown to exist.

Response The present program of vadose zone and groundwater monitoring should be continued. The monitoring program will continue into the future to provide an assessment of contaminant transport during cleanup operations. Because existing contamination from previous activities at the Hanford Site is not within the scope of the EIS, references to the current program of vadose zone and groundwater monitoring are found in other documentation. However, the TWRS EIS does address the cumulative impacts of vadose zone contaminants from past-practice tank leaks, the EIS alternatives and other current and reasonably foreseeable actions at Hanford. Cumulative impacts are presented in Volume One, Section 5.13. Please refer to the response to Comment numbers 0072.08, 0030.02, 0091.01, and 0012.15.

Comment Number 0045.02

USDOE

Comment Page 4-13, Section 4.2.2.2, second paragraph, second sentence: As assumed recharge rate of 0.1 sediment/year (cm/yr) is used for the 200 West Area. However, a recent recharge map (Dresel et al., "Hanford Site Ground-Water Monitoring for 1993" [PNL-10082] DEIS Vol. 4, Appendix F), indicates recharge from precipitation for much of the 200 West Area is from 5 to 10 cm/yr. This is probably due to engineering/regrading of much of the surface materials which has removed the fine-grained sediments and vegetation, leaving coarse-grained, unvegetated surfaces. Also, page I-22 (Section I.2.2.2.1, second paragraph, second sentence) states that an average recharge rate of 0.1 cm/yr was used for the 200 West Area recharge calculation. However, the previous paragraph on this page states that a rate of 10 cm/yr would not be unreasonable for the tank farm areas. This should be clarified in the Final EIS.

Response Infiltration varies temporally and aerially. Infiltration in the 200 Areas is reported to range from near 0 cm/yr where the ground cover is a shrub-steppe type characteristic of predevelopment conditions to 10 to 13 cm/yr where the ground is unvegetated sand and gravel; characteristic of conditions around the tank farms since the mid-1940s or later.

The temporal variation occurs seasonally with the change in temperature, plant activity, and precipitation. It also varies with climatic change. The spatial variation occurs with changes in vegetation, surficial soil type, and human-made structures such as paved parking lots. In response to infiltration rate changes, the vadose zone flow field varies temporally and spatially. However, it is not directly measurable with conventional techniques and is calculated with the model based on vadose zone parameters and assumed infiltration rate. There is also a lag time between a change in infiltration rate at the surface and a change in the flow field in the vadose zone as the water percolates into the ground.

For each alternative, the initial infiltration rate (i.e., the rate before remediation and for the No Action and Long-Term Management alternatives) is assumed to be 5 cm/yr. This assumed initial infiltration rate is within the range of reported values for the Hanford Site and is appropriate given: 1) the recent ground cover changes in the tank vicinity; 2) uncertainties in future ground cover conditions; and 3) the one-dimensional vadose zone flow and transport model used for the simulations. Also, for alternatives that include a cap, the sensitivity analysis in Volume Five, Appendix K of the Final EIS shows that the contaminant transport through the vadose zone is not sensitive to the initial infiltration rate.

From a temporal perspective, the higher infiltration in the vicinity of the tanks is a relatively recent occurrence as stated in the comment. This infiltration increase is in response to the ground cover changes that have occurred within the last 50 years. The relatively recent changes in ground cover are not expected to have changed the flow field at depth within the vadose zone from that of predevelopment conditions. For alternatives involving a cap, conditions after the cap is installed are assumed to be representative of predevelopment conditions in that infiltration in the tank vicinity would be low (e.g., a few millimeters/yr). Infiltration is assumed to remain at 5 cm/yr for the No Action and Long-Term Management alternatives.

Spatially, the rate would be lower away from the tanks where vegetation is allowed and surficial soils are of a finer texture. The one-dimensional model used for contaminant transport simulations through the vadose zone does not account for these infiltration changes with time and space. Thus, the assumed infiltration rate of 5 cm/yr was chosen as a conservative estimate. Because the information contained in the Draft EIS is correct, no change to the text was made.

Comment Page 4-14. First full paragraph, second sentence: The previous comment regarding the 200 West Area recharge also applies to the 200 East Area [Comment number 0045.02].

Response Please refer to the response to Comment number 0045.02.

Comment Number 0069.01

Pollet, Gerald

Comment In 1989 our organization asked then Senator Adams and Congressman Don Bonker to ask the General Accounting Office to do a study of the Department of Energy's claims that leaks from the single-shell high-level waste tanks quote "pose no threat to human health or the environment" unquote, and quote "pose no threat to groundwater" unquote. The Department of Energy continues to make that claim essentially, and bases much of this EIS on that claim today. As you can see, in 1989 the General Accounting Office said in fact tank leaks imperil the Columbia River. That tank leaks are likely to be heading towards groundwater today, if they haven't already reached it, and will flow into the Columbia River. What the department was told, specifically, was that its studies predicting the eventual environmental impact of tank leaks do not provide convincing support for DOE's conclusion that the impact will be low, or nonexistent. This has been ignored in this EIS.

Response Volume One, Section 4.2 and Volume Five, Appendix I describe the affected environment and document that substantial groundwater contamination is known to occur at the Hanford Site and beneath the 200 Areas. The groundwater impacts analysis has predicted that all of the TWRS alternatives would have some impact to groundwater quality and, hence, a potential adverse impact to human health under certain future Site uses scenarios, ranging from relatively low such as for the In Situ Vitrification alternative to quite high as for the No Action alternative. Please refer to the response to Comment numbers 0012.01, 0012.15, 0091.01, and 0030.02.

Because the information requested in the comment was included in the Draft EIS, no modification to the document is warranted.

Comment Number 0069.02

Pollet, Gerald

Comment The General Accounting Office also said that although DOE's maintained that the environmental impact of leaks will be extremely low, or nonexistent, the studies we reviewed do not provide convincing evidence that this is the case. New evidence, available to the Department of Energy because it was collected by its own contractor, available to the people preparing this EIS, and from which is from the Department of Energy presentation, shows underneath the tanks, that are called the SX Tank Farm, cesium-137 is detectable far below the tank, at 125 feet, basically, where it shouldn't be according to this Environmental Impact Statement. Where it isn't, and will not be, according to this Environmental Impact Statement, until we're all dead. But it is there today.

And here is another visualization of the cesium plume at depth. And here is a logging of the contamination in a bore hole, down to 125 feet. This is the ground level, this is the bottom of the tank. Here you have a massive spike far below the tank, and another massive spike right here at nearly 125 feet. And you say, now wait a minute, the Department of Energy says it will take 130 years at least for the waste to get from here to groundwater. Yet it is at massive concentrations at the bottom of bore holes, 125 feet below the tanks already. We are wondering if the Department of Energy has additional evidence, and is sitting on that evidence until after the public comment period is over, as to what other tank wastes might be beneath the tanks, and moving to groundwater as we speak. This is the Department of Energy's own presentation. It is a significant contradiction to the current model, that cesium-137, that's the radionuclide which is very radioactive, does not migrate far from the leak source. It tears apart this Environmental Impact Statement. What would be much more reasonable is if this Environmental Impact Statement was redone on the basis of an assumption that it takes in the vicinity of 25 years for tank leaks to reach groundwater, and from thence to the river is a matter of 10 to 25 years. The clock is ticking.

Response DOE is implementing a program to obtain the emerging information concerning contaminants beneath the SX Tank Farm, but complete resolution of the issue may not occur for more than a year. These data and others were evaluated for consistency with the groundwater impact assessment approach and for identification of other potential active contaminant transport mechanisms in the vadose zone. The results of these evaluations are provided in Volume Five, Appendix K. Please refer to the response to Comment numbers 0012.15, 0012.01, and 0030.02 for additional information and extensive discussion on the evaluation of contaminants beneath the tanks. Please refer to the response to Comment number 0069.01 for information regarding the description of existing Hanford Site groundwater contamination. Please refer to the response to Comment number 0040.06 regarding consideration of vadose zone contamination in the Volume One, Section 5.13 presentation of cumulative impacts.

Comment Number 0072.165

CTUIR

Comment P 5-11: Why do the current drinking water quality standards not apply beyond one thousand years? The people of the CTUIR will be here one thousand years from now and may be impacted.

Response The cited statement is incorrect and has been revised in the Final EIS. The drinking water standard is not limited to 1,000 years. Please refer to the response to Comment number 0036.17.

Comment Number 0072.166

CTUIR

Comment P 5-12: bullet 5: The CTUIR technical staff do agree that this bullet is a major assumption.

Response DOE and Ecology acknowledge the comment but believe it should be retained in the Final EIS.

Comment Number 0072.167

CTUIR

Comment P 5-19: Sect. Contaminant Groups: Of the one hundred contaminants was their mobility determined using the K_d of chelating agents such as EDTA?

Response The mobility of the contaminants for the impact analysis presented in Volume Four, Appendix F does not include the potential effects of chelating agents. The potential effect that chelating may have on contaminant mobility has been incorporated into the Final EIS in Volume Five, Appendix K. Please refer to the response to Comment number 0012.15.

Comment Number 0072.237

CTUIR

Comment P F-10: Sect. F.2.2: There are several assumptions that reduce the effectiveness of this section including, the assumption that there will be only residuals in tanks and vitrified LAW. The other options such as total tank inventory are not explored. This is unfortunate because a substantial portion of total tank inventory is assumed to already have leaked. Ignoring the leaked fraction will change the risk results. Additionally there is new evidence that the leakage is not a vertical conduit, but has regions that resemble lateral spread, such as with the caliche layers at depth.

Response DOE and Ecology are concerned with the total risk associated with past and future releases from the tanks. The groundwater impacts assessment focuses on those impacts associated with the range of future TWRS remedial alternatives. These evaluations are provided in Appendix F, Section F.3. Assessments of cumulative impacts, including the potential impacts from past tank leaks are provided in Volume One, Section 5.13 and Volume Four, Section F.4.5. For discussion of closure issues that are beyond the scope of the EIS, including past leaks from tanks, please refer to the response to Comment number 0072.08.

Some lateral spreading of contaminants in the vadose zone is expected to occur given the layered nature of the sediments at the Site. The one-dimensional model used in the groundwater impacts assessment did not account for lateral spreading, and does provide conservative predictions of contaminant concentration at the vadose zone/groundwater interface. Conservative predictions mean that the predicted contaminant concentrations are higher than would be predicted had a model been used that included lateral spreading. A discussion of potential contaminant transport mechanisms in the vadose zone and their impacts on the alternatives are discussed in Volume Five, Appendix K. Please refer to the response to Comment number 0012.15 for additional information and discussion on the topic of contaminant transport in the vadose zone.

Because the information requested in the comment was included in the Draft EIS, no modification to the document is warranted.

Comment Number 0072.238

CTUIR

Comment P F-11: Sect. F.2.2.2: within this section there should have been discussion related to chelating chemicals such as, EDTA, in regards their ability to mobilize metals. Please include a discussion regarding this both here and in the uncertainty section.

Response Please refer to the response to Comment numbers 0072.167 and 0012.15.

Comment Number 0081.06

Pollet, Gerald

Comment I'd also like to submit for the record relevant pages from the United States General Accounting Office report of 1989 regarding tank leaks. And I hope that we have captured the dialogue sufficiently from this evening for the record, so the record will reflect our concerns about the use of any assumption as to the travel time for tank leaks to groundwater. We believe that tank leaks to groundwater travel time in this EIS should be based on the assumption that it takes 25 years or less for tank leaks to reach groundwater. And that the entire vadose zone, not just the tank itself, needs to be looked at as part of integrated system in this EIS.

Response Please refer to the response to Comment numbers 0069.01, 0069.02, and 0012.15.

Comment Number 0083.02

Pollet, Gerald (Exhibit)

Comment The TWRS EIS and USDOE's proposal to leave wastes in tanks forever is based on the false assumption that tank leaks do not move rapidly through the soil to groundwater and the Columbia River.

In 1989, the U.S. General Accounting Office (in a report initiated by Heart of America Northwest) found that the USDOE's claims that tank leaks would not contaminate the groundwater and the Columbia River were false.

The Draft TWRS EIS ignores new evidence found by a USDOE contractor team, headed by a former whistleblower, which found extremely radioactive cesium, 125 feet below the ground near tanks that have leaked.

Response The recently emerging information was discussed in Volume One, Section 3.3 of the Draft EIS. Additional discussions, based on data that became available after the Draft EIS was published, has been included in the Final EIS in Volume One, Section 4.2; Volume Four, Appendix F; and Volume Five, Appendix K. Please refer to the response to Comment numbers 0040.06 and 101.05 regarding cumulative impacts. Please also refer to the response to Comment numbers 0030.01, 0069.01, 0069.02, and 0012.15.

Comment Number 0089.06

Nez Perce Tribe ERWM

Comment Page 3-4, Paragraph 1

Results from the current TWRS Vadose Zone Characterization and Monitoring Project in the Tanks Operations Division, indicate that cesium-137 is much deeper in the vadose zone than previously estimated. Cesium nitrate and other cesium salts are quite soluble and if absorption sites on soil particles are occupied by other more attracted ions, nothing will impede the movement of cesium to groundwater. Compounds like ammonium and potassium may replace and release soilbound cesium and initiate further cesium migration. This problem highlights a need for more research and vadose zone monitoring.

Response DOE and Ecology acknowledge this need. The mechanism for transport of these contaminants is currently being investigated with additional boreholes. The source term associated with past leaks is much larger, in terms of liquid released per unit time, than any of the conditions associated with any of the alternatives, including No Action. Thus, the presence of cesium at depth may be partially explained by the large liquid loss associated with some of the past leaks. Also, please refer to the response to Comment numbers 0012.15 and 0030.02.

Comment Number 0089.08

Nez Perce Tribe ERWM

Comment Page 3-38, Paragraph 3

The Hanford Barrier may not be fully adequate as a means of isolating tank waste from the environment. Although the barrier may be successfully used to isolate near surface waste in a dry environment, we do not advocate barrier use to isolate deep-seated contaminated waste beneath 200 Area tanks. The barrier may not halt moisture flow under the barrier along impermeable zones. It will not isolate deep-seated contamination from the probable rise in groundwater elevation if local plans to irrigate on the Hanford Site are realized.

Response A very simple infiltration model would have infiltrating precipitation moving vertically through the vadose zone with no lateral spreading. This is not the case at the TWRS facilities given the layered sediments, caliche layers, and potential vertical and horizontal features associated with clastic dikes. Infiltrating precipitation is expected to have some lateral spreading as these various layers and features are encountered. Knowing this allows for the appropriate design of the Hanford Barrier, particularly the lateral extent of the barrier. Past leaks and other closure issues will be addressed in future NEPA analyses for tank closure. For a discussion of the related closure issue, please refer to the response to Comment numbers 0019.04, 0089.08, and 0072.08.

Deep-seated contamination beneath the tanks would have little impact from irrigation given the observations from groundwater mounding associated with U Pond and B Pond, in conjunction with the assumption that irrigation will not be allowed at or near the TWRS facilities. Observations of the extent of the groundwater mound associated with U Pond on the western portion of the Site indicate that the lateral extent of groundwater level rise is limited to the near vicinity of the surface water application. This happens because of the relatively low permeability of the vadose zone soils in the U Pond area. In the 200 East Area and the eastern portion of the 200 Areas Plateau, the vadose zone soils are more permeable. Water level rise from surface applications (e.g., ponds or irrigation) are expected to be relatively flat with a relatively large lateral extent as indicted by the groundwater mound associated with B Pond. In some important ways, the impact assessment provided in Volume Four, Section F.3.0, could be representative of a future extensive irrigation scenario because it is based on 1979 water level data; a point in time when the B Pond and U Pond groundwater mounds were near their highest point. The discharge from these ponds would correspond to extensive irrigation in these areas. For this EIS, it was assumed future land use would prohibit irrigation near the TWRS facilities. Future NEPA analyses for closure would include the potential land use activities.

Comment Number 0089.13

Nez Perce Tribe ERWM

Comment Page F-9, Paragraph 4

The Distribution Coefficient (K_d) of cesium-137 and strontium-90 are discussed as being quite high and therefore not subject to travel from tank leaks through the vadose zone and into the groundwater. Recent information from the Tank Farms Vadose Zone Characterization Project indicates cesium has traveled much further than what would be expected with a K_d of 51, and in fact has already reached groundwater. Information from the vadose zone characterization effort indicates the K_d of cesium may be between 0.7 and 13. A possible cause for the lower than expected K_d may be other ions competing with cesium for adsorptive space on the soils. For example, ammonium and potassium have higher affinity for soil particles than cesium and will preferentially replace and free cesium facilitating cesium movement through the vadose zone. A future irrigation scenario will provide many of the above cesium releasing ions. This information implies more risk to down gradient sources from cesium than the EIS indicates; and we suggest you consider this data.

Response Tank contaminants such as sodium could compete for cation exchange sites in the vadose zone with the result of other contaminants such as cesium (the transport of cesium is retarded primarily by cation exchange) being transported at a rate faster than predicted. Potential mechanisms such as this and many others were assessed. A discussion of the potential causes of the recently emerging information on cesium in the vadose zone was added to Volume Four, Appendix F and Volume Five, Appendix K. Please refer to the response to Comment numbers 0012.15 and 0032.02.

Comment Number 0089.14

Nez Perce Tribe ERWM

Comment Page F-66, Paragraph 1

It states the groundwater modeling approach, based on the December 1979 groundwater level data is conservative in light of uncertainties of waste disposal, future land use, climate change and uncertainty in the depth of contamination in the unconfined aquifer. It is not clear that the modeler has accounted for the amount of water added the water table by irrigation and the amount of increase in groundwater table elevation that could occur. Moisture infiltration at sites where irrigation is initiated will increase from a few centimeters per year to several feet per year. Such activities will greatly multiply the speed of unconfined groundwater movement flooding and mobilizing previously soilbound contaminants within the vadose zone. Modeling completed for the Final EIS should give irrigation scenarios more weight.

Response Irrigation that occurs to the west of the Site is accounted for indirectly via the boundary conditions established at the Cold Creek and Dry Creek drainages onto the Site. The potential for irrigation near the tanks, increasing water levels, multiplying the speed of unconfined groundwater movement, and mobilizing previously soilbound contaminants within the vadose zone will be addressed in a future NEPA analysis on closure. For a discussion of the closure issue, please refer to the response to Comment numbers 0101.06, 0019.03, and 0005.17. Please also refer to the response to Comment numbers 0089.15 and 0089.03, which discuss future land use and irrigation, respectively. Because the information contained in the Draft EIS is correct, no change to the text was made.

Comment Number 0089.15

Nez Perce Tribe ERWM

Comment The most important modeling assumptions and uncertainties are listed. Not included in this list are uncertainties related to land use such as irrigation, which in our view, is the most important uncertainty parameter.

Response Land use issues such as irrigation are important parameters and have been added to the list of important assumptions. It is difficult to predict future land use. For the impact analysis in this EIS, the areas adjacent to the TWRS facilities are not expected to be irrigated. Under some irrigation scenarios, the vadose zone could become thinner due to rising groundwater levels. This would result in a shorter contaminant transport time to the aquifer. Additional thinning of the vadose zone at the TWRS is unlikely, given the observations from groundwater mounding associated with U Pond and B Pond in conjunction with the assumption that irrigation will not be allowed at or near the TWRS facilities. Please refer to the response to Comment numbers 0089.14 and 0089.08 for a discussion of the potential management of irrigation and EIS modeling assumptions.

Comment Number 0090.02

Postcard

Comment Please listen to us say no:

to ignoring hard evidence that Hanford's High-Level Nuclear Waste leaks will poison the groundwater and the Columbia River.

Response DOE and Ecology acknowledge the concern expressed in the comment and are committed to a remediation plan that is protective of groundwater and the Columbia River. Emerging information on leaks from the tanks are being evaluated and are incorporated in this EIS primarily in Volume Five, Appendix K and Volume Four, Appendix F. Future information on tank leaks will be addressed by NEPA analyses for tank closure. The predicted impacts to the groundwater for all alternatives are provided in Volume Four, Section F.3.0. The cumulative impacts of past tanks, the TWRS alternatives, and other actions on groundwater quality are addressed in Volume One, Section 5.3 The predicted impacts to the Columbia River are provided in Volume One, Section 5.2.2.2. Using the bounding assumptions of minimum 7-day mean river flow, time of maximum contaminant discharge to river (500 years for Long-Term Management alternative), and highly mobile contaminants, it was found that there would be a slight increase in contaminant levels, but drinking water standards would not be exceeded (see Volume One, Section 5.2.2.2). The preferred alternative, Phased Implementation, was not analyzed for Columbia River impacts because the contaminant release for this alternative is only about one-tenth of that released for the Long-Term Management alternative. Please refer to the response to Comment numbers 0091.01, 0030.02, 0012.15 and 0072.08.

L.5.2.2 Surface Water

Comment Number 0073.02

Yazzolino, Brad

Comment You haven't, the people that picked that spot were thoughtful in the sense that yes they found a place with nearly 3 miles of volcanic strata underneath it that is relatively hard, but it of course has relatively soft areas in between it. But the river is sitting on top of all that hard material. The basalt. And so are your tanks. And so it's simply, if you would just apply childhood physics to this matter, you have a rock hard basin with the tanks sitting up on the surface. And you have a very tremendous and powerful river sitting next to those tanks. And that river, if you'll all study the Missouri floods, that very well respected theory, but geologically provable, that river about 11,000 years ago for a period of 2,000 years was flushing water over the top of the Hanford, as I call it, peninsula, at a level of probably more than 800 feet deep. So with the coming atmospheric affects that may take place due to global warming, no one can actually predict whether you will, in the next 4 or 5 hundred years. And I think you need to take a longer term, 130 years. Shame on you all. Does radioactivity observe those kinds of microseconds? No, and you all know that. And you need to begin to face the long life of radioactivity, and the long life of the river. So, in the next 4 or 5 hundred years your likely to see floods on the magnitude overtop the section of Hanford that you have your tanks in. Now that's why you need to move that stuff out of there. It needs to be moved. And of course it costs billions. But these are the things humans are good at, these kind of projects.

Response The current and foreseeable future climatic conditions would preclude catastrophic flooding of the TWRS facilities. This conclusion is supported by the analysis provided in Volume One, Sections 4.2 and 5.2; Volume Four, Appendix F; and Volume Five, Appendix I.

L.5.3 AIR QUALITY

Comment Number 0072.28

CTUIR

Comment The emission estimates were not documented.

Response Emission estimates were provided in the Engineering Data Packages for the various alternatives, which are available for public review in DOE Reading Rooms and Information Repositories. Emission rates were calculated from these emission estimates using the construction and operating schedules presented in the packages. The resulting emission rates are presented in Volume Five, Appendix G. Emission calculations in tons emitted for each constituent are contained in the references shown in Volume Five, Appendix G. Because the information requested in the comment was included in the Draft EIS, no modification to the document is warranted.

Comment Number 0072.29

CTUIR

Comment No onsite receptors were evaluated and no risks were calculated.

Response Onsite receptors were evaluated and risks were calculated in Volume One, Section 5.11 and Volume Three, Sections D.4, D.5, and D.6 of the Draft EIS in Volume Three, Appendix D. A rectangular grid of 834 receptors, which encompasses the entire Hanford Site, was used to evaluate potential air impacts onsite. The risk associated with potential air impacts, along with those from other media evaluated (groundwater and soil), was calculated for each exposure scenario evaluated and presented in Volume Three, Appendix D. Risk contour maps are presented in Volume Three, Section D.5 of the Final EIS.

Comment Number 0072.30

CTUIR

Comment Only a small subset of released constituents were modeled.

Response The pollutants presented in Volume One, Section 5.13 represent a small subset of the pollutants modeled. The results presented were for the pollutants that contributed to impacts. The complete list of pollutants and the modeling results are located in Volume Five, Appendix G. Because the information requested in the comment was included in the Draft EIS, no modification to the document is warranted.

Comment Number 0072.31

CTUIR

Comment There was no recognition that tank farms are only part of the annual Hanford dose; some apportionment is needed.

Response In Volume One, Section 2.0, Purpose and Need for Action, it is stipulated that this EIS addresses Hanford Site tank waste and encapsulated cesium and strontium to reduce existing and potential future risk to the public, Site workers, and the environment. An assessment of the contamination at the entire Hanford facility (Sitewide assessment) would facilitate apportionment of the contribution of TWRS. The Sitewide assessment is not within the scope of this document; consequently, no apportionment is presented. However, Volume One, Section 5.13 does address potential cumulative impacts of TWRS alternative emissions with emissions from ongoing and reasonably foreseeable activities. Please refer to the response to Comment number 0072.243. Because the information requested in the comment was included in the Draft EIS to the extent appropriate for the TWRS analysis, no modification to the document is warranted.

Comment Number 0072.32

CTUIR

Comment Particulate deposition should be included, since this is part of the annual NESHAPs reporting requirement.

Response The inclusion of particulate deposition in air emission modeling would reduce airborne concentrations and thus minimize offsite impacts. Ignoring the effect of particulate deposition results in a conservative estimate of air emission impacts. Particulate deposition was accounted for in the determination of anticipated risks to the general public due to ingestion of vegetation, meat, and milk contaminated by airborne deposition, as discussed in Volume Three, Appendix D. Because the information requested in the comment was included in the Draft EIS, no modification to the document is warranted.

Comment Number 0072.239

CTUIR

Comment P G-2: Sect. G.2.1: It is not clear whether fugitive emissions are included in the Area Sources. The relation between Stack/Fugitive-Area and Normal/Unplanned releases (per NESHAPs) should be made clearer. Are the stack numbers the same as those reported in the annual NESHAPs report? Is there a 1:1 correspondence between all the sources in the EIS and the NESHAPs reports? Please clarify the regulatory framework. For each source, please add the anticipated duration of operation or emission for the various alternatives (also add columns to the tables after the emission rate columns).

Response This comment contains six sections, each with its separate explanations. For clarity, each explanation has been given a number.

1. When fugitive emissions are included in the Area Sources, the text of the EIS points this fact out. In the Draft EIS, Volume Five, Section G.2.1, the following area sources associated with fugitive emissions are specifically called out: Waste Retrieval Annexes Areas, page G-3; and Process Facilities and Tank Farm Construction, page G-5.
2. All emissions are considered under National Emissions Standards for Hazardous Pollutants (NESHAPs) regardless of their source. There is no relation between Stack/Fugitive-Area and Normal/Unplanned releases, because all contribute to the emissions from the Hanford Site.
3. Because the stack designations used in the EIS are for air modeling and environmental planning purposes and have therefore not been constructed, they will not be found in the annual NESHAPs report.
4. The sources in the EIS are of a conceptual nature. The exact sources that will be active during construction and operation would be determined during final design. Consequently, there is no correspondence between the sources in the EIS and the NESHAPs reports.
5. The regulatory framework of the EIS is explained in detail in Volume One, Section 6.0. In particular, the relevant environmental requirements are detailed in Volume One, Section 6.1.
6. The anticipated durations of the construction and operating phases for each alternative are shown by alternative in Volume Five, Section G.2.2, Model Scenarios.

Because the information requested in the comment was included in the Draft EIS, no modification to the document is warranted.

Comment Number 0072.240

CTUIR

Comment P G-13: Sect. G.3.1.2: Please forward information regarding particle sizes, Ranges, densities, and deposition rates for this section. This information was not in the tables referenced. Additionally filter failure rates should also be included.

Response A study conducted on cooling towers (Wistrom and Ovard 1973) shows the size of particulate matter (PM) emitted from cooling towers to range from 20 µm to 2,400 µm. Particles larger than 450 µm settle out within 400 feet from the tower. Approximately 30 percent of tower emissions are less than 450 µm and may drift offsite. These particulates will decrease in size as the water drop evaporates.

Particulate matter nominally 10 micrometers (µm) or less (PM-10) emissions associated with construction mainly are due to engine exhaust and fugitive dust. AP-42 Table C.2-2 (Wistrom and Ovand 1973) shows that 95 percent of PM due to engine combustion is smaller than 10 µm and 90 percent is smaller than 2.5 µm. Fugitive dust emissions tend to be smaller than 30 µm with 20 to 40 percent less than 10 µm, depending on source.

Radiological PM emissions emitted from HEPA air filters will be much smaller than 10 µm. The term HEPA was designated by the U.S. Atomic Energy Commission for filters that are at least 99.97 percent efficient by volume on 0.3 µm particles (Austin and Timmermann 1965). A control efficiency of 99.95 percent per filter was assumed in the Engineering Design Packages, which are cited in the EIS and available for reviews in DOE Reading Rooms and Information Repositories. Particle size data, densities, and deposition rates from the various emission sources are currently not available.

Comment Number 0072.241

CTUIR

Comment P G-13: PP 3: What are the filter failure rates for the tank farms and the WESF?

Response WSRC-TR-93-262 gives a recommended value of 5.0E-07 per hour for failure from rupture under regular operating conditions (4.4E-03 per year). The HEPA filtration systems have monitoring and alarm systems. If the filter plugs or blow out, the differential pressure gives indication. HEPA filter failure accidents are not covered in Volume Five, Appendix G but in Volume Four, Appendix E, Accident Analysis.

Comment Number 0072.242

CTUIR

Comment P G-15: Sect. G.3.1.4: No onsite receptor locations were evaluated. Since parts of the Hanford Site will be accessible to the public well before the 100 year assumed duration of Site-wide institutional controls is up, some on-site receptors should be added. Public dose limits apply to Site visitors as well as to the offsite boundary receptor. The only points of compliance indicated in this section were the Site boundary and the nearest residence. Although this is conventional for NESHAPs reporting, it is unacceptable for this EIS.

Response Sitewide institutional controls are designed to protect the public and restrict public access to areas of the Site that may pose a risk. In deciding which areas may be open to the public, a detailed assessment of potential exposure must be made and compared to the public dose limits then in effect. A discussion of anticipated health effects both during and after remediation may be found in Volume One, Section 5.11. Contour maps of potential health effects from air released during remediation are presented in Volume Four, Appendix E and Volume One, Section 5.11. Please refer to the response Comment number 0072.29.

Comment Number 0072.243

CTUIR

Comment P G-18: PP 2: The NESHAPs citation (40 CFR 61, Subpart H0 applies to *the entire Hanford Site as a single source*, not to a single program, activity or Area. Therefore, the proper comparison of air modeling results is not to the upper limit of allowed dose, but to a fraction of that limit. NRC uses the term "apportionment" (see, for instance, the WIPP permit) to set limits for individual activities within a larger unit; in the case of WIPP, the storage facility is not allowed to exceed 25 percent of the overall source term. The federal total dose limit for offsite receptors is 100 mrem (all pathways) and 10 mrem (inhalation only). This limits applies to the entire Hanford Site, and the ROD must specify what portion of this limit can be "filled" by TWRS activities. The 1 mrem contour (Phase 2, for instance) occurs in locations where non-rad workers work, and that are outside the bounds of the 200 Area. There is a second impact zone offsite (Ringold area, on the other side of the Columbia River) that will be of concern during actual operations.

Response The 40 CFR 61 Subpart H exposure limit is applied to the Site as a whole. As part of the Hanford Site Air Operating Permit, the annual potential emission from each discharge point has been identified. NESHAPs compliance is based on exposure at the nearest actual residence. Inhalation pathway exposure for the nearest resident for the

TWRS alternatives ranges from 0.019 to 2.4 mrem/yr as shown in Volume Four, Tables G.4.0.20 to G.4.0.30. For 1994, the nearest resident received 0.01 mrem by the inhalation pathway from all Hanford Site emissions (PNL 1995). Assuming the other Site facilities emissions continued at the 0.01-mrem/yr rate, the inhalation pathway exposures for the Site, including the TWRS alternatives, would range from 0.029 to 2.41 mrem/yr (0.019 plus 0.01 mrem/yr to 2.4 plus 0.01 mrem/yr). To be conservative, the TWRS EIS analysis also was performed for hypothetical residences at currently unoccupied locations along the Columbia River and Highway 240. All of these hypothetical residence locations were calculated to be below 1 mrem/yr (10 percent of the 10-mrem/yr NESHAPs) except for the In Situ Vitrification alternative, which was 18.8 mrem/yr at the maximum location. The potential for this exposure could be mitigated by including such measures as continued restriction on location of residences in the subject area.

However, because there are no residences at these hypothetical residence locations, the NESHAPs of 10-mrem/yr would not apply and there would be no exceedance. Volume One, Section 5.13 contains an analysis of the cumulative air quality impacts of the TWRS alternatives and other Site activities. Because the information contained in the Draft EIS is correct, no change to the text was made.

Comment Number 0072.244

CTUIR

Comment P G-36: Table G.3.1.2: No rationale is given for the selection of non-radiological constituents. Please do not refer us to endless other documents - the TWRS EIS is a stand-alone product that will be the sole basis of the ROD. It must provide complete information for evaluation. In particular, the document "Jacobs 1996" that is cited as the basis for the emission estimates is not publicly available, and may not have received any peer review at all. Presenting table after table of emission rates without any explanation is meaningless, and CTUIR cannot accept any results based on such unsupported data.

Response Incorporation of technical data and information by reference is used as a means to limit the volume of the EIS. Referenced supporting technical data, including Jacobs 1996, are publicly available in the Administrative Record and were provided to DOE Reading Rooms and Information Repositories during the Public Comment Period. An independent technical review of the Draft EIS was completed and a copy of this report is available in the TWRS EIS Administrative Record. This independent technical review found that data used in the analyses were derived from valid and fully documented sources that were traceable, and models used to predict impact analyses either were EPA-approved or accepted by experts as fundamentally sound.

Non-radiological constituents and emission rates for current operations (including the No Action alternative) at the tank farm were derived from the Hanford Site Air Operating Permit Application, which covers existing tank farms and evaporator operation. The selection of non-radiological constituents was based on measured emissions from monitoring instrumentation or tank vapor space sampling results. Constituents and emission rates for waste treatment operations addressed in other alternatives were derived from material balance calculations developed for each alternative.

Comment Number 0072.245

CTUIR

Comment P G-57: Table G.3.1.20: Only 5 radionuclides were used for some of the air modeling. 10 nuclides were used for other alternatives, without any explanation. Various sets of hazardous air pollutants were also used. Since the tank contents do not change between the various alternatives, this is illogical. This entire section must be improved.

Response The tables cited in Volume five, Appendix G provided radionuclide emission rates for the alternatives presented in the EIS. The tables showing five radionuclides were based on radionuclides presently reported by the tank farm operations groups. Because no additional information is available, these radionuclides form the basis for emission rates for alternatives where no activities are performed on the tank contents, (i.e., No Action, Long-Term Management, In Situ Fill and Cap). For the remaining alternatives, there is additional information on radionuclide emissions in the flowsheets contained in the engineering data packages. Where additional information is available, additional radionuclides are shown in the tables for a particular alternative, along with the source (e.g., process plant stack). The hazardous air pollutants referred to in the comment are shown in the preceding tables. The tables for No Action, Long-Term Management, and In Situ Fill and Cap alternatives show the emissions presently reported by the tank farm operations groups. The tables for the remaining alternatives show emissions during construction and operation, which are both taken from the engineering data packages. Construction emissions are those anticipated from use of heavy equipment on the Hanford Site. Operating emissions are those given in the flowsheets in the engineering data packages, which are available for review in DOE Reading Rooms and Information Repositories. Because the information contained in the Draft EIS is correct, no change to the text was made.

Comment Number 0072.246

CTUIR

Comment P G-21: Sect. G.5.3: No description of the presumed filter efficiency (and failure rates), particulate size range and deposition rates were given. Additionally, no consideration whatsoever of the long-term impacts of deposited material (either radiological or nonradiological) was given. If deposition rates had been evaluated, there would have been high impact areas identified (Gable Mountain and White Bluffs). Since federal NESHAPs reporting requires deposition and incorporation into agricultural products as part of the annual dose evaluation, corresponding calculation should be presented in the EIS. If they are not, it will be impossible to demonstrate that any of the alternatives will, in fact, be able to meet compliance limits.

Response Routine emissions are discussed in Volume One, Section G.3.1. HEPA filter efficiency was factored into the emission rates provided in the engineering data packages that support routine emissions. HEPA filter failure accidents are discussed in Volume Four, Appendix E, Accident Analysis. Please refer to the response to Comment number 0072.241.

Dose evaluations from routine emissions are not covered in Volume Five, Appendix G, but are discussed in Volume Three, Appendix D. The intent of Appendix G is to access whether or not the air emissions are in conformance with air quality standards. Please refer to the response to Comment numbers 0072.32, 0072.239, and 0072.240 for related information. Because the information contained in the Draft EIS is correct, no change to the text was made.

Comment Number 0072.247

CTUIR

Comment P G-33: Fig. G.4.0.12: Even without any deposition being included, it is apparent that there are high concentrations at the high elevations on Gable Mountain and Rattlesnake Ridge. This means that tribal members visiting those sites will receive a greater exposure than the general public. Further, more deposition will naturally occur at these higher elevations, thus placing these culturally important areas and the people who visit them at increased risk. This section must be revised and linked to socio-cultural impacts.

Response DOE and Ecology acknowledge the concern regarding potential concentrations of radionuclides on Gable Mountain and Rattlesnake Ridge. Further information on the short-term impacts of air emissions during operation of TWRS facilities is contained in Volume Five, Figures G.4.0.1 through G.4.0.12. At higher elevations, predicted concentrations and dose values could be somewhat greater than in the lower elevations, in the immediate area. For areas near Gable Mountain and Rattlesnake Ridge, predicted radionuclide doses are well below the Washington State Acceptable Source Impact Levels (ASILs) and radionuclide dose limits established by State and Federal standards. It would be reasonable to conclude that, even if the predicted doses are somewhat greater at higher elevations, these doses would not be expected to exceed State or Federal standards. The long-term impacts of remediation on Tribal members are addressed in a separate Native American scenario presented in Volume One, Section 5.11 and Volume Three, Appendix D. For information on this scenario, please refer to the response to Comment numbers 0072.198 and 0072.225 for post-remediation accident impacts.

Comment Number 0072.248

CTUIR

Comment P G-20: Sect. G.5.2.2: No description of the actual vitrification operations was given including temperatures, feed materials, emissions, air pollution control device efficiency, effects of startup, trial melts, upsets, and maximum rated capacity. The recent vitrification event at Savannah River should serve as an indication of anticipated variances in emissions.

Response A description of the vitrification operations is provided in Volume Two, Appendix B and was based on information in the referenced Engineering Data Package, which is available for review in the DOE Reading Rooms and Information Repositories. Please refer to the specific data package for vitrification to obtain the most detailed information available. Emissions are based on design rates for the equipment, which should represent peak emissions. Average operating rates (and emissions) are estimated to be approximately 40 percent of the design rates. The information requested in the comment is a level of detail that DOE and Ecology believe is not necessary for meaningful discrimination among the alternatives.

Comment Number 0072.249

CTUIR

Comment P G-83: Tables G.4.0.1-19: these Tables seem to have been prepared solely for reporting purposes and have no identifiable relation to dose and risk. Each individual contaminant is compared to a regulatory level, but no other information is presented. The concentrations vary from 1 hour to annual averages, again without explanation as to whether this assumes maximum continuous operation, or something else.

Response As is stipulated in Volume Five, Section G.5.3 (page G-21), these tables were used to screen the potential impacts associated with air contaminants at the Site versus applicable regulatory (State and Federal) levels. The tables compare the modeling results to the Federal and State standards. The maximum 1-hour average concentration that resulted from the modeling was converted to 3-, 8-, and 24-hour average concentrations to compare to applicable standards when appropriate. The 1-hour average concentration was multiplied by 0.9 to obtain the 3-hour average, 0.7 for the 8-hour average, and 0.4 for the 24-hour average (EPA 1992b).

Predicted maximum emissions for hazardous air pollutants and pollutants for which a Washington State ASIL exists are provided along with the applicable level in Tables G.4.0.1 through G.4.0.19. Some of the pollutants evaluated have Washington State ASIL of Federal Standards reported for 1-hour, 3-hour, 8-hour, or 24-hour concentrations. For instance, PM-10 has a Federal and State 1-, and 8-hour standard. Consequently, for carbon monoxide, the 1-hour model predicted concentration was adjusted by multiplying it by 0.7 to obtain an 8-hour concentration. Because the 1-hour concentration can be altered by multiplying it by the appropriate conversion factor; a conservative estimate of the contaminant concentration is available for comparison to the applicable standards. The modeling results for all alternatives show no exceedances of Federal or State air quality standards for criteria pollutants, hazardous air pollutants, or radionuclides. Because the information requested in the comment was included in the Draft EIS, no modification to the document is warranted.

Comment Number 0072.250

CTUIR

Comment P G-83: Tables G.4.0.19: Groundshine must be included in the evaluation, with and without an assumption of intervention, and with varying degrees of intervention success.

Response Table G.4.0.19 is not in Volume Five, Appendix G on page G-83 as indicated; it is on page G-105. It is assumed the commentor is to referring to Tables G.4.0.1 to G.4.0.19. Because the constituents presented in Tables G.4.0.1 to G.4.0.19 are not radioactive, these constituents would not contribute to a groundshine pathway. However, Tables G.4.0.20 to G.4.0.30 compare the maximum dose per year from radiological constituents with State air quality standards (the purpose of Volume Five, Appendix G is to measure air emissions against air quality standards). The radiological releases do not exceed the air quality standards so intervention would not be required. The groundshine pathway was included in the evaluation of remediation risk to onsite and offsite receptors. Results of the remediation risk evaluation are presented in Volume Three, Appendix D. These results indicate that the impacts from groundshine are orders of magnitude less than from inhalation. The additive impact from groundshine, therefore, would not change the maximum dose shown in Volume Five, Tables G.4.0.20 to G.4.0.30 and no change to the document is warranted.

Comment Number 0072.251

CTUIR

Comment P G-12 - P G-19: Sects. G.3.0 and G.5.1: This section provides insufficient detail about modeling methods. Exposure assumptions must be presented, as well as assumptions about the particulate size range and respirable fraction used in the dose estimation.

Response The model used for this investigation is the Industrial Source Complex Model (ISC2). The model is a Gaussian dispersion model, which can be used for estimating the concentration of pollutants at a receptor. The model is a guideline air quality model accepted by the EPA for regulatory applications. The assumptions in Gaussian dispersion modeling are as follows.

- Pollutant emissions are continuous.
- Mass of pollutants released remains in the atmosphere during transfer from the source to the receptor.
- Meteorological conditions do not change.
- Diffusion in the downwind direction is negligible in comparison to transfer by the wind. Thus diffusion occurs in only the vertical and crosswind directions.
- Time averaged concentrations in the crosswind and vertical direction are assumed to be distributed normally.

ISC2 was run using the standard rural dispersion coefficients. Standard EPA procedures were followed and the regulatory default option was used. The options implemented included the following:

- Final plume rise that accounts for the effective height of the source of emission;
- Buoyancy-induced dispersion that allows for the plume size to increase at the stack exit point;
- Default wind profile exponents;
- Default potential temperature gradients; and
- Upper bound values for building downwash.

The respirable fraction of particulates is assumed to be those with diameter less than or equal to 10 µm (PM-10). Respirable particulates that are greater than 5 µm typically are trapped by hair follicles in the trachea and never reach the lungs.

The risk calculations for each exposure scenario are calculated in Volume Three, Appendix D. For the residential farmer exposure scenario, the exposure parameters for inhalation are as follows:

Inhalation rate - 20 $\frac{m^3}{day}$

Exposure frequency - 365 $\frac{day}{yr}$

Exposure duration = 6 yrs (child)
24 yrs (adult)

Body weight = 16 kg (child)
70 kg (adult)

Averaging time = 365 $\frac{day}{yr}$ * 30 yr

The exposure parameters for each scenario evaluated are presented in Volume Three, Appendix D. Because the information requested in the comment was included in the Draft EIS, no modification to the document is warranted.

Comment Number 0100.01

WDOH

Comment First, Washington's standard for radioactive air emissions is CAP-88. CAP-88 should be used for the modeling in the EIS.

Response There were several reasons why EPA's preferred radionuclide dose model was not used in this analysis. While portions of the dose calculation methodology of the Clean Air Assessment Package-1988 (CAP-88), as well as other site-specific models such as GENII, may have been incorporated in the risk assessment, the air dispersion algorithms of those models were not. The ISC2 was selected as the general air dispersion model for the following reasons:

- ISC2 is a sophisticated model with capabilities comparable to CAP-88, such as the ability to account for a wide spatial separation of many varied source types;
- ISC2 is an EPA guideline model, and was the choice for assessing traditional pollutants (e.g., dust and combustion products) and air toxic emissions;
- Use of ISC2 for all air dispersion modeling provided for consistency in the EIS; and
- A sitewide compliance demonstration with the radiological standards was not the goal of this EIS.

Volume Five, Appendix G contains a comparison of the ISC2 and CAP-88 modeling results and shows that these results compare closely.

Comment Number 0100.02

WDOH

Comment Second, the state standard for total radionuclides is misstated at 25 mrem/yr.

Response The text in Volume Five, Appendix G has been modified to state that the Ambient Air Quality Standard (WAC 173-480) for the maximum accumulated dose equivalent at any offsite receptor from a commercial nuclear facility is 25 mrem/yr. As a Federal facility, the Hanford Site could be expected to comply with the EPA regulation (40 CFR 61), which limits the maximum predicted dose at the nearest residence to 10 mrem/yr dose equivalent.

L.5.4 BIOLOGICAL AND ECOLOGICAL RESOURCES

Comment Number 0019.12

WDFW

Comment Page 5-64, third paragraph, third bullet. Should include "candidate" category as well.

Response The EIS text presents this key issue of the biological and ecological resources impact analysis in the following sentence: "... potential impacts on plant and animal species of concern (those listed or candidates for listing by the Federal government or Washington State as threatened, endangered and sensitive)."

Comment Number 0019.13

WDFW

Comment Page 5-65, section 5.4.1, first paragraph. WDFW believes it is more appropriate to discuss the percent loss of shrub-steppe within the waste management zone (WMA) to emphasize the impacts to shrub-steppe there. Currently, there is approximately 5,800 acres of undisturbed shrub-steppe within the WMA. Impacts to undisturbed shrub-steppe would range up to 6 percent in the WMA from the TWRS alternatives.

Response The EIS was modified in Volume One, Section 5.4 to add the percentage of undisturbed shrub-steppe that potentially would be affected by TWRS EIS alternatives within the waste management area.

Comment Number 0019.14

WDFW

Comment Page 5-67, Table 5.4.1, Phased Implementation (Total). Impacts do not match what is stated elsewhere in the text. 470 acres is stated here. 540 acres (pg. 5-230) and 690 acres (pg. 5-123) are mentioned elsewhere. Please clarify.

Response The EIS was modified to clarify and correct the potentially affected acreages for the Phased Implementation (Total alternative), based on revisions to the Phased Implementation alternative that occurred since publication of the Draft EIS. Volume One, Table 5.4.1 identifies the total amount of shrub-steppe that would be affected. Volume One, Section 5.4 identifies the total amount of land that would be affected, not only the amount of shrub-steppe. Table 5.14.1 has been revised to indicate that shrub-steppe impacts for the Phased Implementation (Total alternative) would be 94 hectares (240 acres) in the 200 Areas and 140 hectares (350 acres) at the potential borrow sites for a total impact of 240 hectares (590 acres). Volume One, Section 5.7 (page 5-123) indicates that approximately 320 hectares (790 acres) would be the total temporary construction-related land use, including both shrub-steppe and non shrub-steppe areas.

Comment Number 0019.15

WDFW

Comment Page 5-71, section 5.4.2, first paragraph. The nesting period should also include a discussion on passerines (sage sparrow, etc.) and that site clearing would avoid the breeding season for these species. These species also receive protection under the Migratory Bird Treaty Act.

Response The EIS has been modified in Volume One, Section 5.4 to include potential impacts on nesting passerine (songbird) species. Mitigation of potential impacts to these species would be described in the Mitigation Action Plan.

Comment Number 0019.16

WDFW

Comment Page 5-75, section 5.4.5, first paragraph. WDFW concurs with the importance of the McGee Ranch as a wildlife corridor for species migration, proliferation, and genetic diversity. Impacts to the McGee Ranch would have a significant adverse affect on wildlife.

Response DOE and Ecology acknowledge the position of the WDFW on McGee Ranch and addressed the wildlife corridor in the Affected Environment discussion in Volume One, Section 4.4 and Volume Five, Appendix I, and potential impacts to the wildlife corridor under each of the alternatives in Volume One, Section 5.4. It is important to note that the TWRS EIS will not support decisions associated with closure of the tanks and it is only under the hypothetical closure option analyzed in the EIS that adverse impacts to McGee Ranch would occur. Thus, no action taken as a result of this EIS would affect species migrations proliferation, or genetic diversity associated with the corridor. Please refer to the response to Comment numbers 0019.03 and 0072.08 for related information on how closure is addressed in the EIS and related impacts on potential borrow sites.

L.5.5 CULTURAL RESOURCES

Comment Number 0089.16

Nez Perce Tribe ERWM

Comment Page I-60, Paragraph 2

It needs to be emphasized that disturbed areas still have potential to contain cultural resources.

Response The EIS has been modified in Volume One, Section 5.5 to indicate that disturbed areas may contain cultural resources that were not identified during the cultural resources survey. This fact is acknowledged by DOE and Ecology and is the reason why the mitigation measures identified in

Volume One, Section 5.20 of the Draft and Final EIS include a commitment to conduct cultural resource surveys, consult with affected Tribal Nations, and mitigate through avoidance whenever feasible.

Comment Number 0101.03

Yakama Indian Nation

Comment In addition we consider that the actions should assure that cultural values of the Yakama Nation, not directly related to public health and safety or the ecological aspects of the environment, should be protected. These other cultural values stem from what could be termed religious beliefs and are associated with the sanctity of the land forms and other natural resources at Hanford.

To accomplish objective establishment of performance bases, i.e., a valid suite of scenarios to be used in the performance assessments, we consider experts knowledgeable in predicting future possible demographic conditions and societal land use patterns, including intruder scenarios, should be utilized. Delphi methods for polling expert opinions on such subjective topics should be employed. YIN representatives should be involved with this activity to assure the demographers, anthropologists, archaeologists, geologists and other experts having the knowledge to anticipate future conditions adequately incorporate scenarios involving Indian usage of the land, the water and the other natural resources, reflecting historical data as warranted. Without the valid determination of such conditions, including those which may occur and would be limiting with respect to the design confidence level, any of the actions described in the subject EIS may be unfounded and not protective of the public health and safety and the environment. In addition, actions justified as a result of the impact assessments may not meet requirements stemming from cultural values discussed above.

Response Please refer to the response to Comment number 0072.149 for a discussion of consultation with Tribal Nations on the TWRS EIS, and Comment numbers 0072.37, 0072.40, 0072.268, 0072.251, and 0072.53 for discussions of changes to the EIS based on Tribal comments on cultural values, cultural sites, and land uses. The discussion of Treaty rights and privileges has been modified in the Final EIS, based on consultation with the affected Tribal Nations, in Volume One, Section 4.4 and Volume Five, Appendix I. The EIS used reference cases, including the Native American subsistence scenario, for comparative purposes to predict unrestricted future land uses beyond the 100-year administrative control period to 10,000 years. These are incorporated into the Native American User Scenario, which is addressed in Volume One, Section 5.11 and Volume Three, Appendix D. For a complete discussion of this issue, refer to the response to Comment number 0072.149. For discussion of how the EIS addresses environmental justice analysis relative to the Tribal Nations, please refer to the response to Comment numbers 0072.271, and 0072.252.

In response to this and other comments by affected Tribal Nations, the risk assessment for the EIS was revised to include an evaluation of anticipated post-remediation risk to a Native American subsistence user of the Hanford Site. Inclusion of a Native American scenario in the Draft EIS was not feasible because a methodology for the assessment had not been developed sufficiently to be incorporated into the Draft EIS. The scenario used for the analysis was developed through consultation with representatives of the affected Tribes and included discussions regarding societal land use patterns, the intruder scenarios, and demographic conditions. Please refer to the response to Comment number 0072.198, which contains a complete discussion of the information included plus a document reference list regarding the addition of a Native American scenario. Please refer to the response to Comment number 0072.225 for a discussion of post-remediation accident impacts to Tribal Nation sacred sites and cultural values.

L.5.6 SOCIOECONOMICS

Comment Number 0072.33

CTUIR

Comment Counting the number of Native Americans living in the 3 nearest counties does not satisfy the Environmental Justice Executive Order or DOE policy.

Response As discussed in the response to Comment number 0072.53, the EIS environmental justice analysis provides demographic data in Volume One, Section 4.6 on Native Americans, as well as low-income and minority populations within an 80-km (50-mi) radius of the Hanford Site Central Plateau. This area includes portions of 10 counties in Washington and Oregon. Volume One, Section 5.19, Environmental Justice, presents a review of all TWRS alternatives' impacts on the natural and human environment that were addressed throughout Volume One, Section 5.0 to determine whether any potentially disproportionate and adverse impacts would occur to the identified minority or low-income populations, including Native American populations. Volume One, Section 5.20 identifies potential mitigation measures that DOE could adopt to address potential environmental justice impacts identified in Section 5.19. Please also refer to the response to Comment numbers 0072.252 and 0072.149.

Comment Number 0072.34

CTUIR

Comment Economic impacts of accidents were not included.

Response The model used to analyze economic impacts incorporates historical data on Tri-Cities socioeconomic conditions to test its results (e.g., the accuracy with which the model, using historical data yields output for past employment that agrees with known past employment levels). The model was then applied to future Hanford Site employment under each alternative to estimate area employment, housing prices, and taxable retail sales. Total area employment estimates were used to estimate impacts on public services. This analysis was presented in Volume One, Section 5.6.

DOE's Recommendations for the Preparation of Environmental Assessments and EISs (DOE 1993d) directs that impacts from low-probability events be analyzed with the amount of detail commensurate with their likelihood of concurrence and potential consequence. The likelihood of an accident under the TWRS alternatives that could affect the local economy is low. Further, there are no historical data for the Tri-Cities that could be used to provide a basis for analyzing potential economic impacts of accidents at the Hanford Site. Volume One, Section 5.6 and Volume Five, Appendix H have been modified to explicitly state that economic impacts of accidents have not been analyzed for post-remediation accident impacts. Please refer to the response to Comment number 0072.225 for a discussion of post-remediation accident impacts on Tribal Nation sacred sites and cultural resources and modifications to Volume Four, Appendix E regarding this issue.

Comment Number 0072.35

CTUIR

Comment No costs for storage, mitigation or disposal were included

Response An econometrics model was used for the economic impact analysis in the EIS to assess the impacts of TWRS alternatives. Hanford Site employment is used in the model as the key independent variable, and then equations based on historical data for the Tri-Cities area, are used to forecast the impacts of changes in future Site employment on socioeconomic conditions (e.g., total nonfarm employment, housing prices). Employment associated with TWRS activities such as waste storage and disposal is included in the analysis; thus, the costs of storage and disposal are included indirectly in the socioeconomic analysis. The direct costs of storage and disposal under each alternative are provided in Volume One, Section 3.0 and Volume Two, Appendix B. Please refer to the response Comment number 0072.225 for a discussion of the impact of mitigation of post-remediation accidents. Because the information requested in the comment was included in the Draft EIS, no modification to the document is warranted.

Comment Number 0072.36

CTUIR

Comment Jobs and housing as the only socioeconomic measures is unsatisfactory.

Response In addition to jobs and housing, the EIS socioeconomic impact analysis includes impacts on taxable retail sales, population, and a wide range of public facilities and services, including schools, police and fire services, medical services, solid and sanitary waste disposal systems and electricity and natural gas energy services in Volume One, Section 5.6 and Volume Five, Appendix H. Because the information requested in the comment was included in the Draft EIS, no modification to the document is warranted.

Comment Number 0072.252

CTUIR

Comment P H-1: Sect H.1.0: The topics covered in this section include the impact on local jobs, impact on the Tri-Party Agreement Milestone schedule, and impacts on demographics, housing prices and similar items. Therefore, we would expect to also see a full treatment of community and tribal quality of life, and intra- and intergenerational equity. This is, in fact, the intent of NEPA and is required under Executive Order 12898. We are aware that scoping discussions pertaining to this type of analysis were held with contractors and Headquarters personnel, yet it is entirely omitted from the Draft EIS.

Executive Order 12898 and DOE Environmental Justice Policy. The Executive Order states that the human health and environment of minority populations must be evaluated, including differential patterns of consumption, social and economic impacts, and whether there is a disproportionate burden of exposures and/or risks on these populations. DOEs Environmental Justice Strategy includes provisions for identifying high risk populations (including subsistence consumption patterns), and for identifying DOE activities that might have a disproportionately high human health or environmental effects on minority populations. This goes far beyond merely counting the number of Native Americans in the three Hanford counties. ***CTUIR expects DOE to consult with technical staff in order to ensure that adverse impacts on a traditional subsistence lifestyle and characterization of populations at highest risk are adequately evaluated for the baseline conditions and for each alternative for as long into the future as the contamination or post-remediation conditions persist..*** The DOE Strategy also directs programs to "encourage ... participation [of American Indian Tribes] in the development of NEPA documents." Since a typical simple "scoping" briefing does not satisfy this directive, and since many of the deficiencies of this EIS could have been anticipated and corrected before publication of the Draft EIS, ***CTUIR further expects DOE to proceed with the revision of the EIS and negotiation of the Record of Decision to genuinely include CTUIR as an equal participant in the decision-negotiation process and in the development of mitigation action plans.***

Response Volume One, Section 5.19 was devoted to a summary of the environmental justice analysis included in the EIS. Volume Five, Appendix H is intended describe the analysis of the socioeconomic impacts of the TWRS EIS alternatives. A summary of this impact analysis is presented in Volume One, Section 5.6. The impacts of the alternatives on other aspects of the human and natural environment are presented in Volume One, Section 5.0 (e.g., air, water, human health, and land use).

The environmental justice requirement states that the environmental justice analysis should be completed to the "extent practicable and appropriate" (EO 12898). In developing the data to support the analysis, the Executive Order instructs agencies to "collect, maintain, and analyze information on the race, national origin, income level, and other readily accessible and appropriate information for areas surrounding facilities or sites expected to have substantial environmental, human health, or economic effect on the surrounding populations." This information is to be used to determine if "programs, policies, and activities have disproportionately high and adverse human health or environmental effects on minority populations and low-income populations."

The Executive Order mandate to collect data that are readily available on the area surrounding the site likely to be impacted by a proposed action and to analyze impacts that may have disproportionately high and adverse effects on minority and low-income populations is consistent with NEPA requirements. NEPA requires that a sliding scale be applied to analysis of potential impacts on the human and natural environment. "The sliding scale approach to NEPA analysis recognizes that agency proposals can be characterized as falling somewhere on a continuum with respect to environmental impacts. This approach embodies instruction that CEQ has provided (40 CFR 1502.1 and 1502.2, for example) with respect to preparation of EISs. The term 'scale' refers to the spectrum of significance of environmental impact. Do not attempt to quantify impacts on environmental resources when it is clear form the context that any impacts would be virtually absent" (DOE 1993d).

For the purposes of complying with the environmental justice and NEPA requirements, the TWRS EIS adopted the following approach to analysis of potential impacts to minority and low-income populations. The data presented in Volume One, Section 4.0 and Volume Five, Appendix I support the environmental justice analysis by describing the affected environment, including potentially affected populations. Consistent with Executive Order 12898 requirements, Section 4.6 and Appendix I identify minority and low-income populations that may be impacted by the proposed action. The second NEPA requirement is to determine the potential impacts of the EIS alternatives on the affected environment. The analysis of potential impacts to the affected environment is presented in Volume One, Section 5.0. This analysis considers the potential impacts on all populations and if an impact would adversely and disproportionately impact minority or low-income populations, the impact was identified.

Based on the analysis of potential impacts to the human and natural environment, the environmental justice initiative requires the agency to determine if any of the impacts would pose a disproportionately high and adverse impact on minority and low-income populations. This analysis is presented in Volume One, Section 5.19. For each area of potential impact (e.g., land use, human health, air quality, water quality) impacts presented in Volume One, Section 5.0 were reviewed to determine if there were any potential disproportionate and adverse impacts to the surrounding populations. If an adverse impact was identified, a determination was made as to whether minority or low-income populations would be disproportionately affected. In the Draft EIS, two potential impacts were identified that would present a concern based on the requirements of the environmental justice initiative. The analysis of the impacts for the Final EIS have been reviewed based on comments and consultation with Tribal Nations. The result of this review has been a modification to the text of Volume One, Section 5.19 to indicate that under all of the alternatives, except No Action and Long-Term Management, certain adverse impacts to sacred sites would occur.

The final requirement of the environmental justice initiative is to mitigate any disproportionate and adverse impacts. In the EIS, mitigation measures that address the environmental justice impacts are addressed in Volume One, Section 5.20. Based on the decision documented in the ROD, DOE will prepare a Mitigation Action Plan, which will document mitigation measures to be implemented

For the Draft EIS, the analysis of human health impacts determined that minority and low-income populations would not be disproportionately and adversely impacted by TWRS actions compared to non-minority and non-low-income populations. However, one area of potential differential impacts could not be fully analyzed in the Draft EIS. This area of potential impacts, long-term risks to human health under a Native American Subsistence scenario, could not be incorporated into the Draft EIS because a methodology for the analysis had not been developed to a level sufficient to support incorporation into the EIS. Subsequent to publication of the Draft EIS, a Native American subsistence scenario has been developed for use on the Hanford Site. Following consultation with affected Tribal Nations, this scenario has been incorporated into the Final EIS. This analysis is presented in Volume Three, Appendix D and summarized in Volume One, Section 5.11. For discussion of consultations with Tribal Nations, please refer to the response to Comment number 0072.149.

Throughout the NEPA process, DOE and Ecology have been proactive in consulting with the affected Tribal Nations regarding the content of the TWRS EIS. Many substantive portions of the Draft EIS were the result of consultation with affected tribes from scoping to the publication of the Draft EIS; just as many of the changes in the Final EIS reflect consultation that has occurred since the Draft EIS was issued for comment. Consultation is a valuable part of the NEPA process. As with any intergovernmental relationship, DOE and Ecology understand that the consultation process requires improvement and will continue to work with the affected Tribal Nations to that end. A proactive consultation process results in the meaningful exchange of technical information between both parties and a shared understanding of the challenges, issues, and concerns that the agencies and Tribal Nations face as they work to improve the environment of the Hanford Site. Please also refer to the response to Comment numbers 0072.53 and 0072.271 for related discussions. Because the information requested in the comment was included in the Draft EIS, no modification to the document is warranted.

Comment Number 0072.253

CTUIR

Comment P H-2: Sect H.1.1: This section deals solely with Hanford employment numbers. We would also expect to see baseline information about local services (for example, school attendance and student-teacher ratios; number of emergency and enforcement personnel per capita, and so on). Various economic impact analysis methods, such as economic base models, econometrics analysis, or input/output models, would require some of this data.

Response Baseline data about local services (e.g., schools, police, and fire services) are provided in Volume Five, Appendix I (Affected Environment), rather than Volume Five, Appendix H (Socioeconomic Impact Modeling). The model used in the EIS uses the historical statistical relationship between Hanford Site employment and other socioeconomic factors (i.e., total nonfarm employment, population, and housing prices) to predict the effects of the TWRS alternatives employment on total nonfarm employment, population, and housing prices. Changes in Hanford Site employment drive the changes in these other socioeconomic aspects of the Tri-Cities area. The model outputs, in terms of future population changes, then were used to assess the TWRS alternatives potential impacts on school enrollments, police and fire services, and other local services. The assessment of impacts on these services was performed by evaluating how the additional TWRS demands on the service systems would affect their ability to meet the total demand (non-TWRS related demands plus TWRS-related demands). This element of the assessment did not involve using the socioeconomic impact model. Please refer to the response to Comment number 0072.36.

Comment Number 0072.254

CTUIR

Comment P H-4: Sect. H.2.0: No documentation for the 2.4 multiplier (2.4. non-Hanford jobs created/lost for each Hanford job) is provided. Various estimates have been used by local civic planners.

Response The socioeconomic impact assessment model uses the historical statistical relationship between Hanford Site employment and total Tri-Cities nonfarm employment as the basis for predicting how changes in future Site employment would affect total area nonfarm employment. The analysis of historical data shows a relationship of approximately 2.4 non-Hanford jobs created/lost (for each Hanford job). This 2.4 multiplier is in reasonably close agreement with employment multipliers used in other Site NEPA analysis. For example, the Final SIS EIS used an employment multiplier of 2.2, based on socioeconomic input/output analysis performed by PNL in 1987 and 1991 (DOE 1995i). The socioeconomic model used for the TWRS EIS also was used for another recent Hanford NEPA document, the HRA EIS. The socioeconomic model used in the TWRS EIS is the most recent model specifically designed to analyze the Tri-Cities economy and incorporated the most recent data available at the time the Draft EIS was prepared.

Comment Number 0072.255

CTUIR

Comment P H-6: Sect. H.2.3: There needs to be identification of the age distribution was used, only total population seems to be here.

Response The socioeconomic impact assessment model utilizes and predicts total population only. The model does not utilize or predict age distribution of the local population. Age distribution modeling would have limited utility in analyzing the relative difference in impacts among the alternatives. For the purpose of this EIS, the only socioeconomic indicator reliant on age distribution in the population would be the impact to public schools in the Tri-Cities area. For this analysis, it was assumed that the age distribution in the future population under each alternative would be the same as the present age distribution (Volume One, Section 5.6). The information requested in the comment is a level of detail that DOE and Ecology believe is not necessary for meaningful discrimination among the alternatives.

Comment Number 0072.256

CTUIR

Comment P H-7: Sect H.2.4: This section needs to be edited to count for accident impacts.

Response The socioeconomic impact assessment model and methodology used for this EIS does not incorporate possible economic impacts of potential accidents. Language has been added to Volume One, Section 5.6 and Volume Five, Appendix H.2.4 to inform the reader that the economic impact analysis does not address potential impacts associated with accidents. The probability of an accident that would have major economic impacts is extremely low, as described in Volume One, Section 5.12 and Volume Four, Appendix E. Please refer to the response to Comment number 0072.225 for a discussion of post-remediation accident impact on Tribal Nation sacred sties and cultural resources. Please also refer to the response to Comment number 0072.34 for a discussion of economic impacts caused by accidents.

Comment Number 0072.257

CTUIR

Comment P H-7: Sect H.3.0: Same comment as above. (See Comment number 0072.256.)

Response Please refer to the response to Comment number 0072.256, 0072.34, and 0072.225.

L.5.7 LAND USE

Comment Number 0036.18

HEAL (Exhibit)

Comment EIS does not deal with most important aspect of permanent land-use commitments.

According to the EIS, there are no potential implications for future land use that need to be dealt with in this EIS. This is because the EIS does not include closure decisions, and Hanford's land use plan is not done. According to the EIS, "No exclusion or restricted use zones have been defined, but this type of land-use issue is expected to be addressed in the land use planning process for the Hanford Site that is currently underway" (p. 5-121). This is a cop-out. The decisions that will be made in this EIS have clear, far-reaching, and critical future land use implications.

The alternatives leave behind waste resulting in risks for future generations that are between significant and downright scary. Some of the alternatives result in risks that absolutely mandate land use restrictions. Potential land use restrictions are a real and important aspect of determining an alternative's impacts.

By limiting the land use commitments to essentially the amount of shrub-steppe that is torn up, the agencies ignore the important health and economic aspects of potential future land use restrictions. In dealing with deadly tank wastes, a few acres of shrub-steppe is nothing compared to keeping Hanford off-limits forever.

Response Volume One, Section 5.7 addresses three distinct land-use implications of the TWRS alternatives. These include permanent land use commitments in the 200 Areas associated with the remedial activities addressed in the EIS, permanent land use commitments in the 200 Areas associated with the potential closure scenario included in the EIS to support a comparative analysis of the alternatives, and land use commitment implications outside the 200 Areas associated with the remedial activities and potential closure scenario.

The impact analysis for commitments in the 200 Areas associated with remedial activities concluded "Temporary and permanent proposed land use commitments for remedial activities under all TWRS EIS alternatives would be consistent with past and existing land uses for the 200 Areas, as well as with proposed use of the area as an exclusive-use waste management area." These land use commitments would range from 0 to 99 acres according to which alternative was implemented and would largely consist of the tank farms and LAW disposal vaults.

For permanent land use commitments associated with the potential closure scenario presented in the EIS, the EIS concluded that land use commitments would include, "the areas that would be covered by the Hanford Barriers under all alternatives except No Action and Long-Term Management." These land use commitments would require approximately an additional 20 to 40 acres beyond those committed under that remedial phase of the implemented alternative.

For land use implications outside the 200 Areas, the EIS indicates that "Groundwater contamination has land use implications. While land uses might not be precluded because of underlying groundwater contamination, the value of land for potential future uses such as agriculture could be diminished or restricted because the underlying groundwater could not be used. Under all EIS alternatives, TWRS activities would contribute to future Site groundwater contamination."

The EIS also states that "No exclusion or restricted use zones have been defined, but this type of land use issue is expected to be addressed in the land use planning process for the Hanford Site that is currently underway." This land use planning process, the CLUP, would consider the implications of the impacts of the TWRS alternatives in the identification of land areas requiring exclusive and/or restricted use. Thus, the information provided in the EIS is a critical part of the land use planning process and provides an important basis for future decisions. When considering the impacts of land use options associated with the TWRS alternatives, land use planners will have available for consideration an extensive amount of information regarding risks to future generations under various land use scenarios. The EIS analyzes health risks associated with alternative land uses in Volume One, Section 5.11 and Volume Three, Appendix D, including residential farmer, industrial worker, and shoreline recreational user. Since the publication of the Draft EIS, a Native American subsistence user scenario has been added to the analysis. For more information on this scenario, please refer to the response to Comment number 0072.198. The EIS also provides information regarding the implications for the waste site intruder or residential farmer who uses waste site drilling spoils site. Finally, the EIS provides data regarding the extent of groundwater contamination that potentially could result from each alternative. All risks and impacts analyzed were extended to 10,000 years into the future.

The EIS does not limit the analysis of land use commitments to "essentially the amount of shrub-steppe that is torn up." None of the land use impacts identified are based on shrub-steppe disturbance as a criteria for determining land use impacts. Rather, for temporary land use commitments, the EIS does identify the amount of land that is not currently disturbed within the 200 Areas that would be needed to support "construction and operating the alternatives and construction activities associated with closure." This land would be unavailable for alternative uses during the period of construction or operations and then after construction or operations was completed. Permanent land use commits land used for waste disposal facilities to permanent waste disposal. These areas become unavailable for alternative uses. Because the information requested in the comment was included in the Draft EIS, no modification to the document is warranted.

L.5.8 VISUAL RESOURCES

No comments were submitted for this topic.

L.5.9 NOISE

No comments were submitted for this topic.

L.5.10 TRANSPORTATION

No comments were submitted for this topic.

L.5.11 ANTICIPATED HEALTH EFFECTS

Comment Number 0005.16

Swanson, John L.

Comment I would like to see the cancer risk estimates presented in the context of comparison with the cancer risk to the involved population due to background radiation and to other "naturally" occurring cancers. I would also be interested in seeing estimated values of something like "dollars per cancer prevented" for the alternatives.

Response The context requested by the comment is presented in Volume One, Sections 4.11 and 5.11, which discuss the effects of radiation on humans, including the cancer risk from exposure to natural or background radiation sources. DOE and Ecology believe that presenting estimates such as dollars per cancer prevented would be inappropriate because such estimates could be construed as a value judgment. The purpose of the EIS is to provide decision makers and stakeholders with a balanced, unbiased assessment of the impacts associated with the alternatives.

Comment Number 0072.197

CTUIR

Comment P D-2: Table D.1.0.1: The first bullet in the post remediation risk is unacceptable because closure was addressed within earlier sections, and the leakage is tank waste leakage, not some other form or source of leakage.

Response The existing contaminants from past practice are not in the scope of this EIS. The impact of closure is not evaluated for this EIS. DOE will conduct an appropriate NEPA review in the future (59 FR 4052). For purposes of comparing the alternatives, a single and consistent method of closure, closure as a landfill, was assumed for all alternatives. This does not mean that closure as a landfill is proposed or necessarily would be selected in the future. Volume One, Section 3.3.1 discusses the closure issue in greater detail. The leakage of tank waste during the remediation is considered in the risk assessment in this EIS. Past tank waste leaks are considered in the analysis of cumulative impacts presented in Volume One, Section 5.13 and Volume Four, Appendix F. For additional information on the relationship between closure and this EIS, please refer to Comment numbers 0072.08 and 0101.06 for discussions of the closure issue and 0030.02, 0091.01, and 0012.15 for a discussion of vadose zone contamination. Because the information requested in the comment was included in the Draft EIS, no modification to the document is warranted.

Comment Number 0072.198

CTUIR

Comment P D-12: Sect. 2.1.3: Please insert a subsistence Native American scenario into this section. The subsistence Native American scenario represents a Native American living on the land subsisting from all the natural resources inherent on the Hanford site. This scenario involves complete acts or activities, is assumed to have access to ground water and is assumed to live anywhere on the site or anywhere along the Columbia River.

Response In consultation with the affected Tribes, a Native American scenario has been developed and used to evaluate the post-remediation risk to a Native American user of the Hanford Site. This scenario represents exposures received during a 70-year lifetime by a Native American living on the land and subsisting on its inherent natural resources. Subsistence activities included in this scenario include hunting, fishing, and gathering of plants and materials. Pathways include those defined for the residential farmer scenario in the Hanford Site Risk Assessment Methodology (HSRAM) (DOE 1995c), plus additional pathways, such as sweat bathing, which represent activities unique to the Native American subsistence lifestyle. The ingestion rates of native foods are based on a combination of EPA-suggested intake rates (EPA 1989b), intake rates used for the Native American scenarios in the Columbia River Comprehensive Impact Assessment (Napier et al. 1996), and data obtained through consultation with the affected Tribes. A complete description of the Native American exposure scenario and the method for its evaluation have been added to Volume Three (Appendix D, Section D.2.1). Results of the post-remediation risk calculations for the Native American scenario have been added to Volume Three (Appendix D, Section D.5.0). A summary of the scenario description and the risk results have also been added to Volume One (Section 5.11.2). For related information on post-remediation accident impacts to Tribal Nation sacred sites and cultural resources, please refer to the response to Comment number 0072.225.

Comment Number 0072.199

CTUIR

Comment P D-14: Please insert the subsistence Native American scenario here.

Response The risk assessment for the EIS was revised in Volume One, Section 5.11 and Volume Three, Appendix D to include an evaluation of anticipated post-remediation risk to a Native American user of the Hanford Site. Please refer to the response to Comment number 0072.198 for more information on the Native American scenario.

Comment Number 0072.200

CTUIR

Comment P D-16: Please insert table D2.1? Exposure pathways included in subsistence Native American Scenario: Subsistence Native American Exposure factors; Subsistence Native American Summary Intake factors.

Response Three new tables containing the data and assumptions used for evaluating post-remediation exposures for the Native American scenario were added to the post-remediation methodology discussion presented in Volume Three, Appendix D, Section D.2.1.3. Table D.2.1.2 presents the exposure pathways included in the Native American scenario, Table D.2.1.3 presents the Native American scenario exposure factors, and Table D.2.1.4 presents the Native American scenario summary intake factors. In addition, please refer to the response to Comment number 0072.198 for more information on the scenario.

Comment Number 0072.201

CTUIR

Comment P D-23: External-exposure route shielding is spelled incorrectly.

Response The spelling error has been corrected in Volume Three, Table D.2.1.6.

Comment Number 0072.202

CTUIR

Comment External-other factors 'shielding' is spelled incorrectly.

Response The spelling error has been corrected in Volume Three, Table D.2.1.6.

Comment Number 0072.203

CTUIR

Comment Same comment as above. (see comment number 0072.202)

Response The spelling error has been corrected in Volume Three, Table D.2.1.6.

Comment Number 0072.204

CTUIR

Comment P D-32: The Strenge-Chamberlain 1995 reference does not differentiate between roots and leafy matter.

Response The risk calculation for all receptors indicates that the contribution of roots and leafy vegetables to the overall risk is very small compared to drinking water. This is demonstrated in the uncertainty analysis developed for the Final EIS and presented in Volume Five, Appendix K.

Comment Number 0072.205

CTUIR

Comment P D-33: The fish ingestion pathway should be based upon the whole fish and not just on what is considered to be 'edible' portions. For further information contact CTUIR technical staff regarding this issue.

Response The concept of edibility varies from culture to culture and Native Americans might consume portions of fish and other animals not commonly consumed by other cultures. The Native American scenario added to the Final EIS, which was developed through consultation with the affected Tribal Nations, includes pathways for ingestion of fish organs, animal organs, and wild bird meat. Intake of fish organs was accounted for by increasing the total fish muscle tissue intake by 10 percent and assuming that contaminated concentrations in fish organs were 10 times the concentrations in fish muscle tissue. Intake of animal organs and wild bird meat was similarly accounted for by increasing the total meat ingestion rate. Please refer to the response to Comment number 0072.198.

Comment Number 0072.206

CTUIR

Comment P D-35: Please re-look at this paragraph, it is awkward and needs to be redone in relation to recent material regarding the Chernobyl accident. Additionally, there is new information regarding genetic affects as presented in NCRP no. 116.

Response Although some epidemiological data for the Chernobyl accident are available in the scientific literature, the studies are not yet complete and the ICRP has not yet issued revised recommendations for hereditary risk factors based on Chernobyl data. The international risk community is now evaluating the hereditary effects of the Chernobyl accident by tracking the incidence of hereditary effects in the progeny of the exposed population and statistically comparing this incidence to that of a nonexposed control population. Until these studies are complete and the ICRP publishes revised recommendations regarding hereditary risk, it would not be appropriate to use Chernobyl data as the basis for an evaluation of hereditary risk.

In response to this comment, the genetic effects information in National Council on Radiation Protection and Measurement (NCRP) No. 116 has been reviewed. This information suggests that the human and animal genetic studies mentioned in the EIS might underestimate the genetic effects of ionizing radiation. The text of the EIS in Volume Three, Section D.2.1.3.3 has been modified to indicate that genetic effects might be greater than indicated by previous human and animal studies, but that the data are not sufficiently validated to permit analysis at this time.

Comment Number 0085.04

Klein, Robin

Comment At the same time, we must act aggressively and do what we can now to prevent further calamity and contamination. Also, the Draft EIS considers these hypothetical users over the next 10,000 years. It is ludicrous to consider such bearing uses, or to consider controls or restrictions for use of soil, groundwater, whatever, so many years hence. Therefore we have a responsibility, an obligation to clean up the site to the fullest extent possible, and as aggressively as we can to reduce spread and impact of the contaminants.

Response DOE and Ecology acknowledge the preference expressed in the comment and will take this preference and other public comments into consideration when making a final decision on remediating the TWRS waste. Consideration of land uses over long periods of time extending into the future was carried out for purposes of comparing alternatives that would have impacts far into the future. The alternatives evaluated represent a reasonable range of alternatives for accomplishing the TWRS mission. Long-term impacts are calculated to support the decision-making process. The EIS also presents short-term impacts associated with implementation of the alternatives and within the 100-year administrative control period. Both long-term and short-term impacts are presented to provide the public and the decision makers with information on environmental and human health impacts that support the comparison of the impacts among the alternatives. Because both short- and long-term impacts are provided, no change to the document is warranted.

Comment Number 0085.05

Klein, Robin

Comment For the record, the anticipated numbers of cancers and fatalities in the Draft EIS that would result from various scenarios and alternatives are a subject of scientific and political controversy in and of themselves, and should not be taken as absolute in this Draft EIS, but rather as relative measures.

Response The risk calculations were performed to support the impact assessment and comparison of alternatives. These risks were not intended and should not be interpreted to represent absolute risks. The Final EIS in Volume One, Section 5.11 and Volume Three, Appendix D presents ranges of risk for each alternative, which provides a better estimate of the potential risks associated with each alternative. For the Final EIS, an expanded uncertainties analysis has been incorporated in Volume Five, Appendix K. This analysis addresses the nominal bounding risk estimate.

L.5.11.1 Remediation Risk

Comment Number 0005.56

Swanson, John L.

Comment One page 5-154 it is said that the cesium and strontium capsules contain no nonradiological chemicals. This is not true; they contain nonradioactive isotopes of cesium and strontium as well as stable isotopes produced on decay of the radioactive isotopes, and also the added chloride and fluoride. (On page 6-22 it is said that these capsules contain hazardous, characteristic, and/or listed wastes).

Response Wording to clarify that the capsules contain chloride, fluoride, and decay products (barium-137 and zirconium-90), in addition to the cesium and strontium, has been added to Volume One, Section 5.11. Risk from nonradiological chemicals during remediation was not evaluated because no nonradiological chemical emissions are associated with any of the capsule alternatives. Wording to clarify this point has also been added to Volume One, Section 5.11.

Comment Number 0028.01

DHHS

Comment The Draft EIS TWRS section dealing with potential adverse human health effects resulting from environmental releases of radioactive or hazardous materials, Volume Three and Appendix D, appears to be well developed and comprehensive:

1. Radiological and hazardous waste exposures to the public from treatment, storage, and disposal operations were estimated using information on waste loads (source terms) and potential at-risk years. Exposure modeling included meteorological data, hydro-geologic data, and potential release scenarios that included both facility and transportation accidents. Pathway modeling included use of GENII-S environmental modeling code. The function and source of each model type are well documented.
2. Risk estimate endpoints for the public included a) cancer incidence from radionuclide and chemical exposures, b) cancer fatalities from radionuclide exposure, c) adverse effects from transportation and/or transportation accidents.
3. Risk from radiological exposures were estimated using ICRP 60 risk factors. The uncertainties in the risk analysis procedure included model uncertainty, scenario uncertainty, and parameter uncertainty (sampling error, data sources).
4. The risk to public health from the transportation and storage of DOE waste materials, as expressed by the Draft EIS TWRS are reasonable.

Response DOE and Ecology acknowledge the comments concerning risk assessment. In response to public comments, the risk assessment has been enhanced by adding a Native American scenario to the evaluation of anticipated post-remediation risk and the analysis and presentation of risk ranges to request uncertainties. Please refer to the response to Comment number 0072.198 for a discussion of the Native American scenario and Comment number 0085.05 for a discussion of risk ranges.

Comment Number 0069.08

Pollet, Gerald

Comment Next, it is wrong to assume that the public in the near term, that is between now and the year 2028, will remain at the Site boundary in calculating risks. Even if you use the Site boundary, the risk calculations are out of date, and fail to consider risks from people using the river, and the new residences that are far closer than the previous north Richland case used.

Response The risk assessment in the Draft EIS addressed users of the Columbia River, the Fitzner Eberhardt Arid Lands Ecology Reserve, and areas of the Hanford Site north of the Columbia River. This information is presented in Volume One, Section 5.11 and Volume Three, Appendix D. The risk assessment in the Draft EIS does not use north Richland as the Site boundary. Rather, the assessment uses a modified boundary, which includes areas likely to be released by DOE in the near future. The maximally-exposed individual receptor is assumed to be located much closer to TWRS contamination sources than north Richland. The site boundary and receptor locations are discussed in Volume Three, Section D.2.2.3. Potential changes in onsite and offsite population and its effect on the risk calculation are addressed in the uncertainties discussion in Volume Five, Appendix K, which has been added to the EIS.

Comment Number 0069.09

Pollet, Gerald

Comment Third, the EIS must clearly show the risk from releases and explosions during the remediation period for each alternative. It's important that you show and use a conservative assumption as to the impact of delay. Throughout the EIS, in determining costs, you use a 40 percent cost contingency factor. In other words the costs are inflated just 40 percent as a contingency. Risk is a function of time, and what is amazing is that there is no contingency factor for time throughout this EIS in calculating risks. So we say that a plant will run 4 years, because that's the design basis for Phase 1 plant. Well if we have a 40 percent contingency for cost, one would also rationally say we might want to have a 40 percent contingency in terms of delay for that same plant. Therefore we have to re-calculate the risks.

Response Risks from releases during remediation were addressed in the Draft EIS in Volume One, Section 5.11 and Volume Two, Appendix D and remediation accidents, including explosions, were addressed in Volume One, Section 5.12 and Volume Four, Appendix E. The EIS analysis used bounding assumptions in analyzing health and accident impacts. A 60 percent efficiency factor was calculated into the remediation operations for each alternative. This assumption is presented in Volume One, Section 3.4.1. This is reflected in the length of operation time for each alternative in the TWRS EIS, and therefore, provides a contingency in the schedule. The probability of an accident (which would drive the risk) is based on the operation duration with the 60 percent efficiency factored in. Based on the assumed efficiency factor, the substance of the comment's suggestion that the EIS use a conservation estimate for facility operations has already been incorporated into the analysis, and therefore no change to the document is warranted. Please also refer to the response to Comment numbers 0072.225 and 0069.09 for discussions of accident risk during remediation and the 100-year administrative period.

Comment Number 0072.17

CTUIR

Comment For each scenario, the airborne release fraction (ARF) and respirable fraction (RF) should be presented separately, not as a single factor, because the nonrespirable fraction would be the fraction that deposits.

Response The airborne release fraction (ARF) and respirable fraction (RF) for planned atmospheric releases, such as would occur during routine TWRS remediation operations, would be the same. This is because planned releases would pass through a filtration system and all particulates that escape the filter would be in the respirable size range. Nevertheless, these particulates would eventually deposit, although they would stay suspended for long periods of time and be dispersed over large areas. The exposure calculation accounts for the contribution from these deposited particles. Please refer to the response to Comment numbers 0072.250, 0072.251, and 0072.17 for related information. Because the information requested in the comment was included in the Draft EIS, no modification to the document is warranted.

Comment Number 0072.207

CTUIR

Comment P D-87: Ground releases resulting in contaminant error concentrations would result in exposure to subsistence Native Americans.

Response The receptors evaluated for the remediation risk assessment (involved worker, noninvolved worker, and general public) were selected to represent a reasonable range of plausible onsite and offsite exposure scenarios that could arise during the construction and routine operational phases of the TWRS program. Because use restrictions and administrative controls would be in place at the Site throughout the remediation period, an onsite Native American scenario is not plausible. Plausible onsite exposures would be to the TWRS workers and noninvolved workers having access to the Site routinely during the remediation period.

Although an offsite Native American scenario is plausible during remediation, the exposures for such a scenario would not differ appreciably from the exposures presented in Volume Three, Section D.4.0 for the general public. This is because the inhalation pathway, which dominates all other pathways in the offsite remediation risk calculation, does not vary between the Native American scenario and the general public scenario. Because the remediation risk for the general public provides a reasonable approximation of the risk to the Native American, risk during remediation to the Native American has not been calculated separately and the EIS has not been changed. For a discussion of inhalation exposure for onsite receptors, please refer to the response to Comment number 0072.29, and for a discussion of inhalation impacts during remediation associated with sacred sites please refer to Comment number 0072.247.

The onsite Native American scenario, although not plausible during remediation, is considered plausible for the period following remediation. DOE and Ecology have developed a Native American scenario in consultation with the affected Tribes. This scenario has been added to the analysis of post-remediation risk presented in Volume Three, Appendix D and Volume One, Section 5.11.2 of the EIS. Please refer to the response to Comment number 0072.198.

Comment Number 0072.208

CTUIR

Comment P D-89: Sect. D 4.2.2: Please indicate what fraction of the Hanford site permit would be the allowable admission rates for the tank farms tank waste retrieval and evaporators.

Response At this time, it is not known what alternative will be implemented, and potential emissions associated with tank waste disposal actions are not covered by existing permits. Once the decision is made, the applicable permits would be obtained including possible revision or amendment of existing permits. Volume One, Section 6.0 discusses possible permitting necessary for implementation of the different alternatives. The chemical emissions for each of the alternatives are presented in Volume Five, Appendix G and are compared with the applicable Federal and State standards or permissible levels. Please refer to the response to Comment numbers 0072.243 and 0072.246 for related discussions. Because the information requested in the comment was included in the Draft EIS, no modification to the document is warranted.

Comment Number 0072.209

CTUIR

Comment P D-102: PP2: Please change dilution to dispersion.

Response Dilution has been changed to dispersion in the discussion of transport for this and all other alternatives in Volume Three, Section D.4.1 through D.4.9.

Comment Number 0072.210

CTUIR

Comment P D-105: What portion of each tank is expected to volatilize during gravel filling. As the tanks liquid is displaced by the gravels mass, raising the liquid level and disturbing the settled contents, a portion of the tanks contents can be assumed to exhale.

Response Tank emissions during gravel filling were calculated and included in the impact assessment. Emission data are provided in Volume Five, Section G.3. Additional technical data are provided in the Administrative Record for the TWRS EIS and are available for public review in the DOE Reading Rooms and Information Repositories locations listed in Volume One, Section 7.0. Because the information requested in the comment was included in the Draft EIS, no modification to the document is warranted.

Comment Number 0072.211

CTUIR

Comment P D-118: Sect. 4.1.1: Please indicate what portion of the overall source term is represented by the tanks contents.

Response One hundred percent of the source term is from the tank contents as presented in Volume Two, Appendix A. Because the information requested in the comment was included in the Draft EIS, no modification to the document is warranted.

Comment Number 0072.212

CTUIR

Comment P D-268: Sect. D.4.14: The mention of accumulation of contaminants in food products indicates that there may have been discussion of Native American food products. Please indicate when and where you have consulted with the affected Tribes regarding this topic.

Response The cited statement refers to a generic source of food products used for the remediation risk analysis. The remediation risk assessment in the Draft EIS addresses risk to the TWRS worker, the noninvolved worker, and the general public, but does not specifically address risk to a Native American receptor. Risk to a Native American receptor during the remediation period would be dominated by the inhalation pathway. For this reason, it would be similar to the risk presented in Volume Three, Appendix D, Section D.4.0 for the general public. The discussion of uncertainty in the risk assessment has been moved from Volume Three, Appendix D to a new Volume Five, Appendix K.

In response to Tribal Nations comments, DOE and Ecology have consulted with the affected Tribes and have developed a Native American scenario for inclusion in the post-remediation risk assessment for the Final EIS. The analysis of post-remediation risk to the Native American receptor has been added to Volume Three, Appendix D, Section D.5.0. Please refer to the response to Comment numbers 0072.149, 0072.55, 0072.198, 0072.207, and 0072.225 for more information on this topic.

Comment Number 0072.213

CTUIR

Comment P D-271: PP1: The consideration that age dependence is not expected to be as important as other factors is unacceptable to the people of the CTUIR whose very lives depend on the health and safety of their elders.

Response The statement regarding age dependency pertains to the internal dose calculation and its sensitivity to the overall dose and risk results. The statement "Age-dependent variations are considered to be less important because the generally higher internal dose factors (ICRP 1975) for the lower age groups are offset by lower breathing and food consumption rates" does not support or oppose the risk response for low or high age groups. For clarity, this sentence has been changed in Appendix D to read "Age-dependent variations are considered to be less sensitive..." In addition, the exposure duration for the Native American scenario added to the risk assessment assumes 70 years instead of the 30 years used for the other receptor scenarios. Please refer to the response to Comment number 0072.198 for related information. The information requested in the comment represents a level of detail that DOE and Ecology believe is not necessary for meaningful discrimination among the alternatives.

Comment Number 0072.214

CTUIR

Comment P D-272: PP 2: This paragraph is confusing, where was the total population evaluated?

Response The population for the onsite and offsite risk calculations is presented in Volume Three, Tables D.2.2.3 and D.2.2.4, respectively.

Comment Number 0090.05

Postcard

Comment Please listen to us say no:

I urge USDOE and the State of Washington to fully calculate the risks of explosions and leaks from any delay in vitrifying these wastes.

Response For a discussion of the relationship between closure, including past tank leaks, please refer to the response to Comment numbers 0012.15, 0072.08, 0101.05, and 0101.06. The risk of tank deflagrations and explosions has been further analyzed by DOE and Ecology for the Final EIS. The results of the new analysis have been incorporated into the Final EIS in Volume Four, Sections E.2.2, E.3.3, E.4.3, E.5.3, E.6.3, E.7.3, E.8.3, E.9.3, E.10.1, and E.10.2. A bounding risk from delay in vitrifying these wastes is presented in Volume Four, Section E.2.2 where the risk is shown from accidents that could result if vitrification is delayed indefinitely under the No Action alternative. Please refer to the response to Comment numbers 0069.10, 0069.12, and 0081.07 for more information regarding risk analysis relative to delays in remediation.

L.5.11.2 Post-Remediation Risk

Comment Number 0009.02

Broderick, John J.

Comment Potential health effects must be reasonable--not zero. There is not enough money to try to clean Hanford so completely that there will be no health impacts. For this reason, the remediation of the tank waste must permit leaving some waste in place with reasonable number of potential health effects.

Response DOE and Ecology acknowledge the preference expressed in the comment and will take this preference and other public comments into consideration when making a final decision on remediating the TWRS waste. Please refer to the response to Comment number 0040.01 for a discussion of factors influencing the evaluation of alternatives. The risk assessment is intended to provide an unbiased analysis of the anticipated health effects associated with the alternatives, and health effects are only one of many impacts analyzed in the EIS.

Comment Number 0012.17

ODOE

Comment Risk Assessment

The risk assessment in the EIS is sufficient to support the proposed action. We do not believe it is sufficient to support any decision which would leave waste in Hanford tanks.

The risk assessment shows long-term substantial environmental and public risks across most of the Hanford Site. The uncertainty in these estimates is so large, we believe the risk assessment should therefore not be relied upon or used as a decision making tool to micro-manage cleanup. It should only be used as a rough measure of the relative effectiveness of the various alternatives at reducing risks. The risks shown are large and justify complete removal and vitrification of all tank wastes.

The risk assessment shows great risk reduction from ISV. It does not however, include the large uncertainty in the technical feasibility of this alternative. ISV has only been demonstrated to a depth of 15 feet in soil. It has not been demonstrated for the depth and areas required for ISV of tank wastes. The risk assessment gives no indication a large uncertainty exists for this alternative. The uncertainty this creates in the ultimate risks is too large for this to be considered a viable alternative.

Response DOE and Ecology acknowledge the preference expressed in the comment and will take this preference and other public comments into consideration when making a final decision on remediating the TWRS waste. Please refer to the response to Comment number 0040.01 for a discussion of factors influencing the evaluation of alternatives.

The risk assessment was conducted to support a comparison of alternatives rather than to determine the absolute risk associated with a particular alternative. Health effects are but one of many impacts considered in selecting the preferred alternative.

DOE and Ecology understand the concern regarding uncertainty and have identified the need to provide additional information in the EIS to clarify the sources and magnitude of uncertainty in the risk calculations. Further uncertainty analysis has been completed and presented in the EIS in Volume Five, Appendix K. Issues concerning uncertainty in the implementability of the ISV alternative are discussed in Volume One, Section 3.4 and Volume Two, Appendix B. The ISV design is recognized as being conceptual in nature and having a high degree of associated uncertainty.

Comment Number 0036.12

HEAL (Exhibit)

Comment Risk from tank waste may be underestimated.

For the preferred alternative, the risk calculations assume that 99 percent of the waste will be retrieved. HEAL supports this assumption and the goal of total retrieval. However, it is unlikely that fully 99 percent will actually be retrieved given current and reasonably foreseeable technologies. Therefore, the risk may actually be much greater due to a larger amount of waste left in the tanks. This is not a request to change this assumption. Rather, it is a point stressing the importance of retrieving all the waste.

Response As is pointed out in Volume Four, Appendix F, Section F.2, the goal of the Tri-Party Agreement is to leave no more than 1 percent of the waste in the tanks after retrieval. Until waste from a sufficient number of tanks has been retrieved, it is not known whether the residual content will be greater or less than the goal of the Tri-Party Agreement. The amount and type of waste that would remain in the tanks after retrieval is also uncertain. The engineering data for the waste retrieval and transfer function common to all ex situ alternatives were developed using 99 percent retrieval as a goal. This information is presented in Volume One, Section 3.4 and Volume Two, Appendix B. The retrieval assumption also included a conservative assumption that the 1 percent residual would be as soluble as the 99 percent retrieved from the tank. This assumption provides a bounding case for impacts to groundwater and health risks under conditions where less that 99 percent of the waste is retrieval. Please refer to the response to Comment numbers 0005.18, 0089.07, 0072.59, and 0076.01 for related information. Because of the uncertainties associated with waste retrieval and the assumptions used in the EIS to bound the impact analysis, no change to the document is warranted.

Comment Number 0036.19

HEAL (Exhibit)

Comment Risk confirms importance of this program.

The high human health risks posed by all of the alternatives emphasize the importance of the Hanford tank waste disposal program. While the uncertainty involved with the EIS's risk calculations is high, the calculations still serve as a rough guide to future health risks.

The EIS shows that the human health risks are directly related to the amount of tank waste left behind. Assuming only 1 percent of the waste is left behind still leaves the farmer at 10,000 years with a 3 in 10,000 chance of cancer. The risk resulting from tank waste being left behind is demonstrated by the Ex Situ/In Situ Combination alternative in which 90 percent of the contaminants are removed by retrieving 50 percent of the waste volume. The risks resulting from this alternative for the farmer at 10,000 years are 3 in 1,000 -- an increase of an order of magnitude over the ex situ alternatives.

The reduction in risk gained in removing 99 percent of the contaminants as opposed to 90 percent shows the importance of the tank waste treatment and disposal program.

Response DOE and Ecology acknowledge the preference expressed in the comment and will take this preference and other public comments into consideration when making a final decision on remediating the TWRS waste. Please refer to the response to Comment number 0040.01 for a discussion of factors influencing the evaluation of alternatives.

Comment Number 0038.04

Reeves, Merilyn

Comment It has also been assumed that the Hanford tank wastes pose a great risk to future generations. And this EIS confirms that assumption.

The EIS shows that the future risk is directly correlated to the amount of waste left behind in the tanks.

The impact of leaving only a small amount of contamination behind is evidenced by the difference in long-term risk for the preferred alternative, where one percent of the waste is left in the ex situ, in situ alternatives, where there is 10 percent left behind, and by leaving nine percent more waste the risk for the residential farmer in 5,000 years increases the factor by 10. These clearly show that the only responsible solution is to retrieve all the waste.

Response DOE and Ecology acknowledge the preference expressed in the comment and will take this preference and other public comments into consideration when making a final decision on remediating the TWRS waste. Please refer to the response to Comment number 0040.01 for a discussion of factors influencing the evaluation of alternatives.

Comment Number 0040.03

Rogers, Gordon J.

Comment I reject dangers to hypothetical intruders as not a realistic concern (for the In Situ Fill and Cap alternative); which is also connected to the administrative control assumption.

Response It is common for purposes of NEPA assessment to assume that government agency administrative controls will end after a period of 100 years. In the absence of administrative controls, there is a probability of inadvertent human intrusion into the waste remaining onsite. To assist in differentiating between the alternatives, and to provide a more complete picture of the health risks posed by leaving waste onsite, the risk assessment included a hypothetical intrusion scenario. The scenario analyzed, well drilling, was considered the most likely intruder scenario. The probability of occurrence of this scenario is evaluated in the uncertainty analysis presented in Volume Five, Appendix K. Please refer to response to Comment number 0101.01 for a related discussion.

Comment Number 0041.02

Berry, Bill

Comment On Appendix D, the long-term analysis of risks, which unavoidably involves uncertainty to the point of being meaningless, assumes that a large industrial facility of 2,200 workers might exist on the Site in the future. The analysis then assumes that the facility would have a land use area of 785 sq. km., yielding a population density of 2.81 individuals/sq. km. Although this analysis may produce a type of average risk assuming the facility could be randomly located anywhere within the 785 sq. km. area (the facility clearly would not require anything near the entire area), a better approach would be siting the facility within the area of highest risk. This approach would provide a bounding estimate of risks to workers in the vent that the future industrial facility was located at the worst possible location.

Response The uncertainties regarding the risk assessment are presented in Volume Five, Appendix K, which has been added for the Final EIS. The industrial worker scenario is not land-area dependent; therefore, in calculating the total risk to the industrial worker, the population density of 2.81 and land use area of 785 km^2 were not used. As discussed in the response to Comment number 0041.03, population density and land use area were needed only for the residential farmer calculation. Volume Three, Table D.5.14.1 has been modified to show that population density and area of land use are not applicable to the industrial scenario. Please refer to the response to Comment number 0012.17.

The comment suggestion regarding the assumed siting of the industrial facility was considered. In response to this comment, the risk to the industrial worker has been recalculated assuming the facility is located in the area of highest risk. The text in Volume Three, Section D.5.14, has been modified to reflect the revised assumption.

Comment Number 0041.03

Berry, Bill

Comment In Table D.5.14.1 the population density for the recreational scenario appears incorrect (1950/104=18.75). I did not check the calculated incidence and fatalities to determine the population density that was used in the calculation. Those numbers should be checked or an explanation of why the lower population density was used should be provided as a footnote with the table.

Response The population density value given in Volume Three, Table D.5.14.1 for the recreational scenario was in error and has been changed. However, the cancer incidence and cancer fatality calculations are correct. To perform these calculations, a value for receptor population was required for each scenario. For the residential farmer scenario, a population estimate was not available; therefore, the population was calculated by multiplying an assumed population density by the Hanford Site area. Population estimates were available for the other scenarios; therefore, a population density was not needed. Population densities are shown in the table for all scenarios for the sake of consistency. The text in Volume Three, Section D.5.14 has been modified to clarify how population density was used in the calculations.

Comment Number 0055.07

Martin, Todd

Comment Moving off of costs, the risks that we see in the EIS are profoundly troublesome to me and I think they under estimate the actual risk. This is not something that I think should be changed, but I think it should be noted. 99 percent retrieval is probably a dubious assumption. It is the correct assumption and it is where we should be going but we are probably not going to get there. In addition, if sluicing does result in more leaked waste we can expect to see much higher risks when you are seeing a residential scenario 10,000 debt years down of three in 10,000 cancer rate with only 1 percent of the waste left behind. Imagine what it is for 2 percent, 3 percent, or maybe 10 percent.

Response As discussed in Volume One, Sections 3.3.1 and 3.4.1, there are many technical uncertainties associated with the alternatives for remediating tank waste. Although the design information for these alternatives is an early planning stage, the technologies represented are considered sufficient to bound the range of viable technologies that are applicable to tank remediation. For purposes of analysis, 99 percent retrieval efficiency was considered a reasonable assumption for the ex situ alternatives. Please refer to the response to Comment number 0036.12 regarding tank waste retrieval assumptions and Comment numbers 0005.18, 0089.07, 0072.59, and 0076.01 for additional discussions regarding the 99 percent retrieval assumption.

Because of uncertainties regarding the amount and type of residual waste that would remain in the tanks, it was assumed for the ex situ alternatives that the residual waste would contain 1 percent of all constituents in the original tank inventory, including the water-soluble constituents. In actuality, the residuals would contain less of the water-soluble constituents because they would be preferentially retrieved through sluicing. The assumption that 1 percent of the water-soluble waste remains in the tanks thus provides an upper bound on the impacts associated with the ex situ alternatives. The In Situ Fill and Cap and Ex Situ/In Situ Combination 1 and 2 alternatives leave more waste in the tanks and provide an upper bound on the impacts associated with the amount and type of waste disposed of onsite. Additional discussion of the uncertainties surrounding retrieval are presented in Volume Five, Appendix K.

Regarding leaks during sluicing, the predicted groundwater contaminant concentrations used for the risk analysis in the Draft EIS were calculated assuming that SSTs leaked a volume of 15,000 liters (4,000 gallons) per tank during retrieval. Detailed discussion of the tank release assumptions used for the groundwater modeling effort is presented in Volume Four, Appendix F, Section F.2.2. For additional discussion regarding this assumption, please refer to the response to Comment numbers 0029.01, 0030.03, and 0072.75.

Comment Number 0069.03

Pollet, Gerald

Comment This is a long-term risk scenario where the risks to people in this area here from groundwater contamination are essentially 1 person dies out of every 100 exposed. And that is without taking into account the type of assumption that should be made for leaks today. That means, the risks are far greater if we leave any tank waste in-place. Call it in situ capping, it's gravel, folks. It's cemented gravel on top of it. It will reach groundwater.

Response For the No Action, Long-Term Management, and In Situ Fill and Cap alternatives, the maximum anticipated post-remediation risk (incremental lifetime cancer risk) reaches levels as high as 1 in 100. However, as shown in Volume One, Table 5.11.4, the post-remediation risk for the other alternatives is anticipated to be less (i.e., no risk or risk less than 1.0E-06).

Impacts associated with past leaks from the tanks, based on data that became available following publication of the Draft EIS, are addressed in Volume Four, Appendix F and in the cumulative impacts discussion in Volume One, Section 5.13. For more information related to this issue please refer to the response to Comment numbers 0012.05, 0030.02, and 0091.01.

Comment Number 0069.06

Pollet, Gerald

Comment Now I come to the issue of risks. The, I'm going to turn this off, Environmental Impact Statement makes a number of assumptions about risks that are clearly erroneous, and out of date as well. First, it apparently uses a recreational exposure scenario for calculating risk, which we have criticized repeatedly recently, of the public using the Columbia River just 56 hours a year. It is ludicrous. In fact, we believe that a rational scenario for recreational exposure is 1,040 hours a year. The risks shown for recreational exposure, and I want to remind everyone that and for the record remind everyone that risk is a function of time, therefore the risks presented for these scenario's are 18 times too low.

Response The exposure scenarios used in the risk assessment were based on the recommendations published in the HSRAM (DOE 1995c). These recommendations have been approved by the signatories to the Tri-Party Agreement for use in Hanford Site risk assessments. In the case of the recreational shoreline user scenario, the HSRAM scenario was modified to increase the exposure duration from one week to two weeks for 30 years. This provided a more bounding estimation of risk than would have resulted from using the HSRAM scenario and is considered by DOE and Ecology to be appropriate. Because the information contained in the Draft EIS is correct, no change to the text was made.

Comment Number 0069.07

Pollet, Gerald

Comment Second point as to this exposure scenarios along the Columbia River, folks where is the Native American Treaty Right usage? It is not presented here. That is a usage, guaranteed by the Treaty of 1855, which one can rationally assume will be asserted during this timeframe, and which allows Native American treaty right tribes to live along this area of the Columbia River, and to gather foods and fish in the usual accustomed places while living along the river for extended periods of time.

Response Please refer to response to Comment numbers 0072.37, 0072.198, 0072.252, and 0072.225 for discussions of the analysis of impacts in response to Comments submitted by Tribal Nations regarding treaty rights, cultural resources, and future land use.

Comment Number 0072.18

CTUIR

Comment No Native American exposure scenario is included. During the revision of the EIS, if such a scenario is added, it *must be preceded by consultation with CTUIR.*

Response The risk assessment for the EIS has been revised to include an evaluation of anticipated post-remediation risk to a Native American user of the Hanford Site. The scenario used for the analysis was developed through consultation with representatives of the affected Tribes. Please refer to the response to Comment number 0072.198 for more information on the Native American scenario. For impacts associated with post-remediation accidents, refer to the response to Comment number 0072.225.

Comment Number 0072.19

CTUIR

Comment Deposition of particulates was not included.

Response The size of the particulates released during remediation would be very fine. These particulates would stay suspended in the atmosphere for long periods of time and would be transported over very large distances. A typical deposition velocity for particulates dispersed in the atmosphere is 1.0E-03 m/s. The post-remediation risk from deposition of particulates released to the atmosphere during remediation is very small. This risk is 3 to 4 orders of magnitude smaller than the inhalation risk during remediation. Anticipated health risk during and after remediation is contained in Volume One, Section 5.11, and Volume Three, Appendix D. Air quality issues are discussed in Volume One, Section 5.3. Please refer to the response to Comment numbers 0072.32 and 0072.240. Because the information requested in the comment was included in the Draft EIS, no modification to the document is warranted.

CTUIR

Comment Genetic effects must be included, both for individual generations and for multiple generations.

Response The health effects endpoints used for the risk assessment (cancer incidence and cancer fatalities) were selected for consistency with other EISs prepared by DOE and with the endpoints used for the accident analysis presented in Volume Four, Appendix E. Cancer incidence and cancer fatalities are the endpoints commonly used for NEPA reviews, where the purpose of the assessment is to compare impacts among alternatives rather than to calculate absolute risks. A calculation of hereditary effects would not affect the ability of the decision makers and stakeholders to discriminate among the alternatives, because the results of the calculations would provide data that would support the same understanding of the relative difference among alternatives as does the existing calculation of cancer occurrences and cancer fatalities. For this reason, the decision to omit consideration of genetic risk from the EIS is considered appropriate, and the EIS has not been changed. The anticipated hereditary effects associated with the alternatives may be calculated by multiplying the radiological doses (rem) presented in Volume Three, Appendix D by the dose-to-risk conversion factor of 1.3E-04 (genetic risk per rem) published by the ICRP in 1991. Please refer to the response to Comment number 0072.206.

Comment Number 0072.21

CTUIR

Comment Existing soil and groundwater contamination was not included in the source term.

Response Existing soil and groundwater contamination are not included in the scope of the TWRS program and were specifically excluded from consideration in this EIS. However, existing soil contamination is addressed, in terms of its cumulative impacts with the TWRS alternatives in Volume One, Section 5.13 and Volume Four, Appendix F. Please refer to the response to Comment numbers 0030.02, 0072.08, 0012.15, 0091.01. Because the analysis requested in the comment is not within the scope of the EIS, no modification to the document is warranted.

Comment Number 0072.22

CTUIR

Comment No evaluation of socio-cultural quality of life was included.

Response Volume Three, Appendix D is the technical support document for analyzing remediation and post-remediation health risks to human health and ecological and biological resources. This appendix does not and was not intended to provide an assessment of quality-of-life issues. The human health analysis presented in Volume Three, Appendix D is summarized in Volume One, Section 5.11. Impacts to ecological and biological resources are summarized in Volume One, Section 5.4.

To the extent that impacts to human health and biological and ecological resources are an indicator of the socio-cultural quality of life, the relative differences in impacts reported in Volume One, Sections 5.11 and 5.4 provide the public and decision makers with information on which a comparison among the alternatives may be formed. This same statement would apply to all areas of impact assessment summarized in Volume One, Section 5.0. In addition to human health and ecological and biological impacts, Section 5.0 documents potential impacts by alternative to geology, air quality, water quality, land use, biological and ecological resources, the economy, public services, and visual effects, among others. In total, the analysis presented in Section 5.0 represents the potential impacts of the alternatives on the human and natural environment and hence on the socio-cultural quality of life.

The broad range of data regarding potential impacts are presented in the EIS so that the public, agencies, Tribal Nations, and decision makers can be aware of potential impacts during the decision making process. It is the role of each of these participants in the decision making process to compare the impacts and apply their values when determining which among the factors that will influence the selection of the alternative to be implemented should be considered in comparison to other factors. The role of the EIS is to objectively present alternatives, provide a comparison of impacts among alternatives, and provide an opportunity for public, agency, and Tribal Nation participation in the NEPA process. Please refer to the response to Comment numbers 0072.37, 0072.53, 0072.271, and 0072.252. Because the information requested in the comment was included in the Draft EIS, no modification to the document is warranted.

Comment Number 0072.23

CTUIR

Comment For ecological evaluation, instantaneous dilution in the River is unacceptable.

Response The ecological impact analysis presented in Volume One, Section 5.4 and Volume Three, Appendix D does not assume instantaneous dilution of groundwater reaching the Columbia River. Potential hazards were estimated for direct exposure to the groundwater before dilution, with organisms using no other water source. Please refer to the response to Comment number 0072.217 for a discussion of dilution factors used in the analysis. Because the information requested in the comment was included in the Draft EIS, no modification to the document is warranted.

Comment Number 0072.24

CTUIR

Comment The ecological dose limits need to be revised (terrestrial is more protective than aquatic), and the ecological Hazard Indexes (HI) that were developed for the EIS need to add a safety factor for sensitive life stages.
